

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

SIR JOHN BRICHSEN DEAD.

One of the Most Prominent of English Surgeons.

LONDON, September 31. — Sir John Eric Brichsen, who was made a Baronet in 1885, is dead.

Sir John Eric Brichsen was born in 1816, and was best known for several works on physiology and surgery, notably "The Science and Art of Surgery," which has been translated into German, Spanish, Italian and even Chinese. Sir John was the unsuccessful Liberal candidate for the Universities of Edinburgh and St. Andrews in 1855. He was formerly president of the Royal College of Physicians and was a Fellow of the Royal Society, the University of New York, the American Surgical Association and other scientific institutions. He was Surgeon-Extraordinary to the Queen, and was president of the University College, London.

PREFACE

TO THE TENTH EDITION.

THE period that has elapsed since the Ninth Edition of the "Science and Art of Surgery" was published has been marked by many important advances in the Pathology as well as in the Practice of Surgery. Due prominence has been given in this Edition to that which is both new and important. No pains have been spared to bring the whole work up to the standard of the most advanced modern Surgery, and this has been done without any very appreciable increase in its bulk.

The premature death of Professor Marcus Beek—*multis ille bonis studiis occidit, nulli debilius quam mihi*—was a great loss not only to the Profession of which he was so distinguished a member, but to "The Science and Art of Surgery" of which he had been so long the able Editor. Learned without being a pedant; scientific and yet practical; a master of the Art but not a slave to the details of Surgery, he was specially well fitted for the task of revising a work such as this. Fortunately, he had left the New Edition in a forward state—nearly one-third of the First Volume being ready for the Press at the time of his death, and much valuable material being collected for the remainder. Mr. Raymond Johnson, his pupil, friend and assistant, was requested to complete the Revision of the Work, to bring it up to date and to carry it through the Press. This, the Author feels confident, he has done in a manner which will fully maintain the character that the work had acquired under the Editorship of his predecessor.

Mr. Meredith has again kindly undertaken the Revision of the

Chapter on Gynæcological Surgery; and Mr. C. Louis Taylor has given valuable assistance in carrying the work through the Press.

The Author is also deeply indebted to Mr. T. W. P. Lawrence, Curator of the Museum of University College, for the care which he has taken in supervising generally the Illustrations of the book, and for many new Figures from his pencil.

Several of the old wood-cuts have been cancelled and re-drawn, and many new ones have been added. In the few instances in which a wood-cut has been copied from another work, the name of the author of the work from which it is taken has been appended to it. When no such acknowledgment is made, the figure is original, belongs exclusively to this work, and except in the case of diagrams has been drawn from nature. The Author may be excused for laying stress on these points, as many of his illustrations have been copied into other works on Surgery without any acknowledgment of the source whence they have been taken.

The Author feels that a responsibility, weighty in proportion to the very extent of the wide diffusion of his instruction, is incurred by him who takes upon himself the task of teaching others that Science which underlies the Art, and that Art, the exercise of which constitutes the application to Practice of a great branch of Medical Knowledge, which more directly than any other Department of Medicine involves the physical well-being, and more immediately affects the life of those on whom it is exercised.

It is not sufficient that the teaching of a Scientific Art, such as Surgery, should be sound in those General Laws that constitute its Principles. It must also be accurate in those minute details that are necessary to its successful Practice, and, above all, just in its estimate of the labours of others.

A Teacher of Surgery, who seeks to give a true and impartial view of the subject of his tuition, is placed in much the same position as a Judge who is summing up a great cause.

He must endeavour to divest himself of the trammels of the Schools—to free himself alike from the partisanship of individual bias and from the prejudice of professional antagonism.

He must lay down clearly the broad General Principles on which the Case rests; set forth its facts in an orderly and succinct manner, draw those deductions which legitimately flow therefrom, and guide his Pupils to arrive at just conclusions by the light of his own more matured and extended experience.

Throughout the Work it has been the object of the Author to place before the Student and Practitioner the Science and Art of Surgery—not as consisting, merely, in the observation of such Injuries, Diseases, and Malformations as are met with in Surgical Practice, or in the dexterous application of manual or operative means for their relief; but as demanding an exercise of general medical knowledge, and a thorough acquaintance with all those conditions, whether intrinsic to the patient, or surrounding him, that favour or prevent his restoration to health. The remarks in the earlier part of the First Chapter will, it is trusted, sufficiently indicate to the Student what is required of him in order that he may become a successful Practitioner of Surgery.

In every instance an endeavour has been made to give as full and clear a description of Symptoms, Pathology, Diagnosis, and Treatment, as the importance of each demands, and the present state of Surgical Knowledge permits.

The various new Operations practised in modern Surgery have been carefully described, the difficulties and dangers attending their performance pointed out, and the cases requiring them detailed.

The paramount importance of Surgical Hygiene, both general and local, has led to special attention being paid to it in the Chapters on Operations, Wounds, and Septic Diseases.

With respect to Diagnosis it may be remarked that, as accuracy in this branch is an all-important requisite for success in Treatment,

not only have the signs and symptoms by which the injury or disease under consideration may be recognized been described in each case, but care has been taken, even at the risk of occasional repetition, to point out the several conditions with which it may be confounded, and the means of distinguishing it from each of them.

More than forty years have passed since the First Edition of this Work appeared. During this lengthened period it has met with no inconsiderable favour in this and in other countries. Nearly forty thousand copies have issued from the Press in this country. Successive Editions have been reprinted in the United States of America, and it has been translated into several of the European Languages. The Author cannot but hope that the present Edition in its amended form will be found deserving of the continued confidence of the Surgical Profession at home and abroad.

JOHN ERIC ERICHSEN.

LONDON, 1895.

CONTENTS OF THE FIRST VOLUME.

DIVISION FIRST.

FIRST PRINCIPLES.

CHAPTER I.—GENERAL CONSIDERATIONS ON OPERATIONS.

	PAGE
OBJECTS OF SURGICAL OPERATION—Present Position of Operative Surgery—	
Medical Dexterity and Scientific Knowledge Required	1—4
CONDITIONS INFLUENCING SUCCESS OF OPERATIONS—State of General Health—	
Hygienic Conditions—Special Conditions excited by the Operation itself	4—16
PREPARATION FOR OPERATION	17—18
GENERAL ANÆSTHETICS—History—Influence on Mortality after Operations—Their	
Administration—Administration of Ether—Secondary Effects of Ether—Death	
from Administration of Ether—Administration of Ether by the Rectum—	
Administration of Chloroform—Secondary Effects of Chloroform—Death from	
Chloroform—Methyl Chloroform, and Ether—Chloroform and Morphia—	
Reduction of Methylene—Nitrous Oxide Gas—Death from Administration of	
Laughing Gas—Nitrous Oxide and Ether—Other Anæsthetics—Comparison	
between Ether and Chloroform—Choice of an Anæsthetic—Administration of	
Anæsthetics during Shock—Treatment of Effects of Overdose of Anæsthetics	18—38
LOCAL ANÆSTHESIA—Cold—Rapid Evaporation of highly rectified Ether—Cocaine	
—Mode of Employment—Cocaine Poisoning	38—40
PERFORMANCE OF AN OPERATION—Incisions	40—44
PREVENTION OF HÆMORRHAGE DURING OPERATIONS—The Tourniquet and its	
Application—Compression by Elastic Tubing or Bandage—Bloodless Methods—	
Compression of Main Arteries	44—54
CONSTITUTIONAL EFFECTS OF OPERATIONS—Local Treatment of Wounds—After-	
treatment—Diet—Remote Effect	54—56

CHAPTER II.—AMPUTATIONS AND DISARTICULATIONS.

PERFORMANCE OF AN AMPUTATION—History—Amputation by Circular Method—	
Trap Amputation—Principles of Amputation—Amputation by the Modified	
Circular Method—Liston's Method—Teale's Operation—Long Anterior Flap—	
Oval Method—sawing the Bone—Amputating Instruments—Arrest of Hæmor-	
rhage—Closure of the Wound—Dressing the Stump—Simultaneous or Rapidly	
Consecutive Amputation of two Limbs	57—76
STUMPS—Structure of a Stump—Artificial Limbs—Morbid Conditions of Stumps—	
Scars—Osteomyelitis—Neurosis—Conical or "Sugar-loaf" Stumps—Aneurismal	
Engagement of Arteries—Painful and Spasmodic Stumps—Recurrence of	
Ulcers—Early Degeneration of Stumps	76—79
MORTALITY AFTER AMPUTATION—Chief Causes—Effect of Age—General Health	
Influence of Shock and Septic Diseases—Effects of Antiseptic Treatment—	
Post-Amputation—Part of Bone—Nature of Disease—Time of Performance	
Primary and Secondary Amputations—Summary	79—92

CHAPTER III.—SPECIAL AMPUTATIONS.

	PAGE
AMPUTATIONS OF THE UPPER LIMB—Fingers—Metacarpo-Phalangeal Articulations—Thumb—Metacarpal Bones—Wrist—Forearm—Arm—Shoulder-Joint—By Transfixion—Lister's Method—Spence's Method—Larrey's Oval Method—Amputation of Arm with Scapula and part of Clavicle—General Results of Amputations of the Upper Limb	93—112
AMPUTATIONS OF THE LOWER LIMB—Toes—Metatarso-Phalangeal Articulations—Amputation of Great Toe—Anatomical Guides in the Foot—Metatarsal Bone of Great Toe—of Little Toe—Amputation of Metatarsus—Hey's Operation—Amputation through Tarsus—Chopart's Operation—Tripiet's Modification of Chopart's Amputation—Subastragalar Amputation—Syme's Disarticulation at the Ankle-Joint—Pirogoff's Amputation—Results of Amputations of Foot—Amputation of Leg—Flap Amputation—Circular Operation—Results—Amputation through Knee-Joint—By Anterior and Posterior Flaps—By Lateral Flaps: Smith's Method—Amputation through Condyles: Carden's and Lister's Operations—Results of Amputation through Knee-Joint or Condyles—Amputation of Thigh—Vernale's Operation—Amputation of Thigh by Antero-posterior Flaps—Combination Method—Through Trochanters—Results of Amputation of Thigh—Amputation at Hip-Joint—By combined Circular and External Vertical Incisions—Antero-posterior Flaps—Oval Amputation—Results	112—147

CHAPTER IV.—LOCAL DISTURBANCES OF CIRCULATION AND INFLAMMATION.

REGULATION OF THE LOCAL SUPPLY OF BLOOD	148—149
LOCAL ANÆMIA	149—150
ACTIVE LOCAL HYPERÆMIA, ACTIVE CONGESTION, DETERMINATION OF BLOOD, OR FLUXION—Active Congestion—Causes—Symptoms—Effects	150—151
PASSIVE CONGESTION—Causes—Effects—Symptoms—Treatment	151—154
STRANGULATION	154
ACUTE INFLAMMATION—History—MICROSCOPIC CHANGES IN: Active Hyperæmia—Stasis—Oscillation—Thrombosis—Migration of the White Corpuscles—Inflammatory Lymph—Migrated Corpuscles in the Tissues—Effect of Inflammation on the Tissues—Micro and Macro Phagocytes.—MODE OF TERMINATION: Resolution—Suppuration—Ulceration—Gangrene.—CAUSES OF INFLAMMATION: Predisposing—Exciting.—IRRITANTS: Mechanical—Physical—Chemical—Products of Putrefaction. SCHIZOMYCETES Micrococci—Bacteria—Bacilli—Spirilla.—ORGANISED IRRITANTS, FUNCTIONAL IRRITATION, NERVOUS IRRITANTS—Varieties of Inflammation—Local Signs.—INFLAMMATORY FEVER—Symptoms of Fever in general—Varieties of Acute Surgical Fever.—IRRITATIVE FEVER	155—201
TREATMENT OF ACUTE INFLAMMATION—Preventive Treatment: Antiseptics—Cold—Rest—Curative Treatment—Local Treatment—Constitutional Treatment—Treatment of Inflammatory Fever: Sthenic and Asthenic	201—223
CHRONIC INFLAMMATION—Pathology—Causes—Local Signs—Constitutional Symptoms—Treatment, Constitutional and Local	223—235
CATARRHAL INFLAMMATION—Pathology—Purulent Catarrh—Varieties—Symptoms—Treatment	235—237

CHAPTER V.—SUPPURATION AND ABSCESS.

SUPPURATION—Formation of an Acute Abscess—Characters of Pus—Microscopic Characters—Diagnosis of Pus from other Fluids—Relation of Micro-Organisms to Suppuration—Duration—Symptoms—Hectic—Albumenoid or Amyloid Degeneration	238—252
--	---------

CONTENTS.

xi

	PAGE
VARIETIES OF ABSCESS—Definition—Acute or Phlegmonous—Chronic—Lymphatic or Congestive—Situation and Size—Pressure Effects—Diagnosis—Prognosis—Treatment—Time of Opening—Treatment of Acute Abscess—Drainage Tube—Treatment of Chronic Abscess—Tapping—Incision—Antiseptic Treatment—Constitutional Treatment of Suppuration—Hæmorrhage into Cavity of Abscess.	
SINUS AND FISTULA—Causes—Structure—Treatment	252—269

CHAPTER VI.—ULCERATION.

ULCERATION defined—Pathology—Causes—Situation—General Treatment—Local—Constitutional	270—275
VARIOUS FORMS OF ULCER—Healthy Granulating Sore—Treatment—Skin-Grafting—Weak—Indolent or Callous—Irritable—Inflamed—Sloughing—Eczematous—Varicose—On Mucous Membranes	275—284

CHAPTER VII.—THE PROCESS OF REPAIR.

MODES OF UNION OF WOUNDS—Immediate Union—Union by Primary Adhesion—By Scabbing—By Granulation—By Secondary Adhesion—Circumstances affecting the Healing Process	285—299
---	---------

DIVISION SECOND.

SURGICAL INJURIES.

INJURIES AFFECTING THE TISSUES GENERALLY.

CHAPTER VIII.—CONSTITUTIONAL EFFECTS OF INJURY.

SHOCK—With Cardiac Inhibition—With Nervous Exhaustion—Symptoms—Pathology of Shock—Causes—Diagnosis—Erectile Shock—Treatment of Shock—Operation during Shock—Prevention of Shock	300—305
TRAUMATIC FEVER—Aseptic—Septic—TRAUMATIC DELIRIUM—Inflammatory—Necrosis—Treatment	305—309
REMOTE EFFECTS OF INJURY—Constitutional—Local	310

CHAPTER IX.—INJURIES OF SOFT PARTS.

CONCUSSIONS—Extravasation—Causes—Degrees—Diagnosis—Treatment—Strangulation of Parts—Spontaneous Wounds	311—315
CUTS—WOUNDS—How Classified	315
SCALD WOUNDS—Symptoms—Management—Local Treatment—Arrest of Hæmorrhage—Removal of Foreign Bodies—Computation—Varieties of Suture—Plasters—Treatment of Wound—Necessity of Rest	315—321

	PAGE
METHODS OF TREATING WOUNDS —Exclusion of Air—Open Treatment—Water, Dry-Lint, and Cotton-wool Dressings—Antiseptic Treatment of Wounds—Carbolic and Eucalyptus Gauze Dressings—Oil with Antiseptic in Solution—Perchloride of Mercury. Sal Alembroth and Double Cyanide, Gauze, Salicylic Wool, and other Dressings—Iodoform Treatment—Inflammation of Incised Wounds	321—333
CONTUSED AND LACERATED WOUNDS —Characters—Sloughing—Gangrene—Treatment—Hæmorrhage—Amputation.— BRUSH-BURN —Treatment	333—340
STABS AND PUNCTURED WOUNDS —Treatment—Arrow-Wounds	340—343

CHAPTER X.—GUNSHOT WOUNDS.

GUNSHOT WOUNDS IN GENERAL —Characters—Nature and Force of Projectile—Direction—Apertures of Entry and Exit—Symptoms—Treatment—Arrest of Hæmorrhage—Extraction of Foreign Bodies—Treatment of Wound—Cases requiring Amputation.— GUNSHOT WOUNDS OF SPECIAL BONES AND JOINTS —Excision in Gunshot Wounds	344—365
--	---------

CHAPTER XI.—POISONED WOUNDS.

STINGS OF INSECTS —Treatment	367
SNAKE-BITES —Effects of Snake-Poison—Symptoms—Treatment	368—370
BITES OF RABID ANIMALS: HYDROPHOBIA —Symptoms—Rabies in the Dog—Rabies in Man—Nature of Virus—Period of Inoculation—Symptoms in Man—Duration and Termination—Prognosis—Pathology—Treatment: Preventive—Excision—Caustics—Pasteur's Preventive Treatment—Palliative Treatment	370—380
MALIGNANT PUSTULE —Symptoms—Diagnosis—Pathology—Treatment	380—385
GLANDERS —In the Horse—In Man—Diagnosis—Pathology—Duration—Prognosis—Treatment	385—387
WOUNDS WITH INOCULATION OF DECOMPOSING ANIMAL MATTER, AND THE PRODUCTS OF UNHEALTHY INFLAMMATIONS —Causes—Symptoms—Treatment	387—391

CHAPTER XII.—EFFECTS OF HEAT AND COLD.

BURNS AND SCALDS —Local Effects—Degrees—Constitutional Effects—Prognosis—Treatment—Prevention and Removal of Contraction—Operations—Warty Cicatrices—Amputation	392—403
FROST-BITE —Local Influence of Cold—Constitutional Effects—Treatment—Chilblain—Treatment	403—405

CHAPTER XIII.—INJURIES OF BLOOD-VESSELS.

INJURIES OF VEINS —Venous Hæmorrhage	406—407
INJURIES OF ARTERIES —Contusion—Rupture and Laceration—Penetrating Wounds	407—408
HÆMORRHAGE FROM WOUNDED VESSELS —Local Signs—Distinctive Characters of Arterial and Venous—Extravasation—Constitutional Effects—General Treatment—Transfusion of Blood	408—412

CHAPTER XIV.—ARREST OF ARTERIAL HÆMORRHAGE.

	PAGE
NATURAL ARREST OF HÆMORRHAGE—History of Investigations—Temporary Means—Coagulation of Blood and Diminution of Heart's Action—Retraction and Contraction of the Artery—Formation of Coagulum—Permanent Closure of Artery—Adhesion—Contraction—Arrest of Hæmorrhage from Punctured or Partially Divided Arteries	413-419
SURGICAL TREATMENT—Temporary Means—Compression of Artery—Tourniquet—Permanent Means—Cold—Hot Water—Styptics—Canterisation—Direct Pressure—Forensic Flexion—Torsion—Torsion and Ligature Compared—Forci-pressure—Ligature—History—Application—Effects of Ligature—Wire and Catgut Ligatures—Carbolized Catgut—Carbolized Silk—Tendon Ligature—Ox-aorta Ligature—Temporary Ligatures—Aenpressure—Collateral Circulation—Principles of Treatment of Primary Arterial Hæmorrhage—Mode of Operating	419-452
ACCIDENTS AFTER ARTERIAL OCCLUSION BY SURGICAL MEANS—Intermediate or Reactionary Hæmorrhage—Causes—Phænomena—Treatment—Secondary or Recurrent Hæmorrhage—Causes—Phænomena—Periods of Occurrence—Prevention—Treatment—Gangrene following Ligature—Causes—Character—Treatment	452-463

CHAPTER XV.—TRAUMATIC ANEURISM AND ARTERIO-VEINOUS WOUNDS.

TRAUMATIC ANEURISM—Diffused—Diagnosis—Treatment. Circumscribed: Treatment	464-470
ARTERIO-VEINOUS WOUNDS—Aneurismal Varix—Symptoms—Treatment. Varicose Aneurism. Pathology—Symptoms—Treatment	470-473

CHAPTER XVI.—WOUNDS OF SPECIAL BLOOD-VESSELS.

VESSELS OF HEAD AND NECK—Carotid Artery—Aneurismal Varix in Neck—Traumatic Aneurism of Temporal Artery—Hæmorrhage from Deep Arteries of Face—Injury of Internal Maxillary and Lingual Arteries—Wounds of Vertebral Artery	474-476
VESSELS OF THE TRUNK—Internal Mammary—Intercostal Arteries	476
VESSELS OF UPPER LIMB—Wound of Subclavian Artery—Aneurismal Varix—Artery Artery. Open Wounds—Traumatic Aneurism—Brachial Artery; Wound—Traumatic Aneurism—Varicose Aneurism—Aneurismal Varix of Arm—Vessels of Forearm and Palm: Traumatic Aneurism of Radial and Ulnar Arteries. Wounds of Palmar Arches—Circumscribed Traumatic Aneurism in Palm	476-483
VESSELS OF LOWER LIMB—Traumatic Aneurism of Gluteal Artery—Femoral Artery—Diffused Traumatic Aneurism—Varicose Aneurism—Vessels of Leg and Foot. Wounds and Traumatic Aneurisms	483-485

CHAPTER XVII.—ENTRANCE OF AIR INTO VEINS.

AIR IN VEINS—Results of Experiments on Animals—Spontaneous Entry in Man—Local Phenomena—Constitutional Effects—Cause—Preventive Treatment—Curative Treatment—Indications to be followed	486-490
---	---------

CHAPTER XVIII.—SPECIAL INJURIES OF NERVES, MUSCLES, AND TENDONS.

	PAGE
INJURIES OF NERVES—Contusion—Puncture—Division—Pathology—Treatment of Injuries causing Interruption of the Conducting Power of a Nerve—Traumatic Neuritis—Pathology—Symptoms—Treatment—Operation of Nerve-stretching—Physiological Effects—Results	491—501
INJURIES OF MUSCLES AND TENDONS—Contusions—Sprains or Strains—Rupture of Sheath—Dislocation or Displacement of Muscles or Tendons—Rupture and Division—Union—Treatment—Injuries of Special Muscles and Tendons	501—506

CHAPTER XIX.—INJURIES OF BONES AND JOINTS.

INJURIES OF BONES—Bruising—Bending	507
INJURIES OF JOINTS—Contusions—Sprains—Treatment—Incomplete Recovery—Pathology of Traumatic Septic Arthritis—Symptoms and Effects—Treatment of Wounded Joints.—WOUNDS OF INDIVIDUAL JOINTS—Hip and Shoulder—Knee—Elbow and Ankle—Wrist	507—516

CHAPTER XX.—FRACTURES.

FRACTURE—Causes—Varieties—Nature—Direction—Separation of Epiphyses—Signs—Diagnosis—Process of Union—Of Simple Fracture—Modification of Union—Clinical Course	517—531
TREATMENT OF FRACTURE—Constitutional Treatment in Simple Fracture—Surgical Treatment—Reduction—Prevention of Return of Displacement—Bandages—Splints—Starched Bandage—Plaster of Paris Bandage—Silicate of Soda or Water-Glass Bandage.—ACCIDENTS AND COMPLICATIONS DURING TREATMENT—Traumatic Delirium—Fat Embolism—Hypostatic Pulmonary Congestion—Crutch-palsy—Spasm—Oedema—Extravasation of Blood—Splint Sores—Gangrene—Shortening of Limb.—COMPLICATED FRACTURES—Treatment.—COMPOUND FRACTURE—Union—Question of Amputation—Reduction—Management of Splinters—Oozing of Blood—Treatment of the Wound—Septic Inflammation and Suppuration—Septic Osteomyelitis—Necrosis of Ends of Fragments—Time for Consolidation—Secondary Amputation—Malposition after Fracture—Delayed Union.—UNUNITED FRACTURE—False Joint—Causes—Treatment—Treatment of False Joint	531—571

CHAPTER XXI.—SPECIAL FRACTURES.

FRACTURES OF THE BONES OF THE FACE.—NASAL BONES—Septum Narium—Lachrymal Bone.—MALAR AND UPPER JAW-BONES—Separation of all the Bones of the Face—Gunshot Injuries of Face.—LOWER JAW—Situations—Signs—Treatment—Fracture of Lower Jaw by Gunshot Injury—Hyoid Bone	572—577
FRACTURES OF THE UPPER EXTREMITY.—CLAVICLE—Complications—Situations—Signs—Comminuted Fracture of Clavicle—Compound Fracture of Clavicle—Treatment of Simple Fracture—Of Comminuted Fracture.—SCAPULA—Fracture of Body of Bone—Near Shoulder-Joint—Acromion—Coracoid Process—Neck of Scapula.—HUMERUS—Fracture of Anatomical Neck—Of Surgical Neck—Compound Fracture of Surgical Neck—Separation of Great Tuberosity—Compound	

and Comminuted Fracture of Head of Humerus—Fractures of Shaft—Near Elbow-Joint—Separation of Lower Epiphysis—Transverse Fracture of Lower End—Fracture of Condyle—Injury of Nerves in Fracture of Humerus—Compound and Comminuted Fractures of Elbow-Joint.—FOREARM Olecranon—Compound Fracture of Olecranon—Coronoid Process of Ulna—Middle of Forearm—Lower Extremity of Radius—Deformity—Mechanism—Treatment—Metacarpus and Fingers 578—604

FRACTURES OF THE PELVIS AND THE LOWER EXTREMITY.—PELVIS—Acetabulum—Symphysis—Coccyx—Coccydynia.—THIGH-BONE—Of Pelvic End—Intracapsular—Cause—Signs—Nelton's Diagnostic Line—Bryant's Iliac Femoral Rectangle—Middle of Union—Treatment—Impacted Intracapsular—Extracapsular Fracture—Unimpacted Fracture—Impacted Fracture—Pathology—Treatment—Diagnosis—Compound Fracture of Neck of Bone—Fracture of Trochanter Major—Of Shaft—Treatment of Compound and Comminuted Fracture—Fracture near Knee-Joint.—PATELLA—Union—Treatment—Splints and Bandages—Operative Procedures—After Effects—Compound and Comminuted Fracture—Necrosis.—BONES OF LEG—Treatment of Simple Fracture—Period of Union—Complications—Compound Fracture of Tibia—Fractures near Ankle-Joint—Pott's Fracture—Signs—Treatment—Dupuytren's Fracture—Internal and External Mal-unions—Compound Fracture into Ankle-Joint—Badly-set Fractures near Ankle.—BONES OF FOOT—Fracture of Os Calcis—Astragalus—Tarsal Bones—Metatarsal Bones 604—642

CHAPTER XXII.—DISLOCATIONS.

DISLOCATIONS DEFINED—Causes—Signs—Effects—Treatment—Mechanical Complications—Manipulation—After-treatment—Dislocations of Old Standing—Treatment—Obstacles to Reduction—Anesthesia—Accidents in Attempts at Reduction—Compound Dislocation—Treatment—Complications—Spontaneous Dislocations—Treatment—Congenital Dislocations	643—656
---	---------

CHAPTER XXIII.—SPECIAL DISLOCATIONS.

DISLOCATIONS OF THE LOWER JAW—Causes—Bilateral—Unilateral—Subluxation—Reduction—Congenital Dislocation	657—659
DISLOCATIONS OF THE UPPER LIMB—Clavicle—Sternal End—Outer End—Simultaneous of both Ends.—SCAPULA.—SHOULDER-JOINT—Signs—Varieties—Subcoracoid—Subclavicular—Subspinous—Subglenoid—Partial—Causes—Relative Frequency—Diagnosis—Reduction—Compound—Complications—Congenital—Unreduced—Accidents in Attempted Reduction.—ELBOW-JOINT—Both Bones—Causes—Reduction—Complications—Diagnosis—Reduction—Compound—Old Unreduced Dislocations—Lower End of the Radius and Ulna.—WRIST—Hand and Carpal—Backward—Forward—Diagnosis—Compound—Congenital.—SINGLE CARPAL BONES—Os Magnum—Pisiform—Scaphoid.—METACARPAL BONES.—METACARPO-PHALANGEAL JOINTS—Thumb—Reduction.—PHALANGES OF FINGERS	659—686
DISLOCATIONS OF THE LOWER LIMB—Pelvis—Pubic Symphysis—Sacro-iliac Articulation—Coccyx—FEMUR—Cooper's Classification—Importance of the femoral Ligament—Bergman's Classification—Varieties—Mechanism of Production—Methods of Reduction—Horse-shoe—Reduction—On Thyroid Foramen—Reduction—On Patellar Bone—Reduction—Subspinous Dislocation—Supraspinous Dislocation—Reduced—Bursal—Irregular Dislocations—Reduction of Old Dislocations—Complications with Fracture—Simultaneous—Spontaneous—Congenital.—PATELLA—Dislocations—Reduction.—KNEE—Varieties—Complications—Compound Dislocation—Congenital Dislocations—Subluxation—Rupture of Posterior Crucial Ligament—Head of Fibula.—ANKLE—Varieties—Compound—Treatment.—ASTRAGALUS—Varieties—Treatment—Compound—SUBASTRAGALAR.—TARSAL BONES—Calcaneum, Scaphoid and Cuboid—Internal Unconform.—METATARSAL BONES—Phalanges of Toes	686—714

CHAPTER XXIV.—INJURIES OF THE HEAD.

	PAGE
INJURIES OF THE SCALP.—Contusions—Cephalhæmatoma—Pathology—Wounds—Complications—Treatment	715—720
INJURIES OF THE SKULL—Bending-in of Cranial Bones—Contusion of Cranial Bones—Causes and Varieties of Fracture— <i>Contrecoup</i> —Fissured Fracture—Fracture of the Base of the Skull—Signs—Hæmorrhage—Discharge of Watery Fluid—Treatment—Depressed Fracture—Varieties—Symptoms—Wounds of the Dura Mater—Treatment of Depressed Fracture—Elevating Depressed Bone—Treatment of Punctured Fracture—Linear Cuts—Ultimate Results of Fracture of Skull—Complication with Injury of Spinal Column	720—742
CEREBRAL COMPLICATIONS OF INJURIES OF THE HEAD—Concussion of Brain—Pathology—Signs—Terminations—Compression of Brain—Symptoms—Diagnosis—Cerebral Irritation—Treatment of Concussion—Coma from Compression—Treatment of Cerebral Irritation—Summary	742—748
CONTUSION AND LACERATION OF THE BRAIN AND ITS MEMBRANES—Causes— <i>Post-Mortem</i> Appearances—Symptoms and Effects—Nature and Locality of Injuries—Results—Diagnosis of Cerebral Laceration—Prognosis—Treatment—Consequences of Injuries of Brain	748—763
COMPLICATIONS OF WOUNDS OF THE BRAIN AND ITS MEMBRANES—Extravasation of Blood within Skull—Causes—Situations—Results—Symptoms—Mechanism of Meningeal Extravasation—Diagnosis—Treatment	763—771
TRAUMATIC MENINGITIS AND ENCEPHALITIS—Causes—Period of Invasion—Pathological Changes—Symptoms—Diagnosis—Treatment—Chronic or Subacute Encephalitis.—INTRACRANIAL SUPPURATION—Subcranial Abscess—Intrame-ningeal Abscess—Cerebral Abscess—Diagnosis—Prognosis—Treatment.—HERNIA OR FUNGUS CEREBRI—Treatment	771—780
SECONDARY OR REMOTE EFFECTS OF HEAD INJURIES—On Mental Powers—Epilepsy—Treatment	780—782
OPERATION OF TREPHINING	782—786

CHAPTER XXV.—INJURIES OF THE SPINE.

CONCUSSION OF THE SPINAL CORD—Definition.—SPRAIN OF THE SPINAL COLUMN—Symptoms.—INTRASPINAL HÆMORRHAGE—Symptoms.—MENINGITIS AND MYELITIS.—GENERAL NERVOUS SHOCK OR TRAUMATIC NEURASTHENIA—Symptoms.—TRAUMATIC HYSTERIA—Symptoms—Affections of the Eye after Spinal Injury—Diagnosis—Treatment	788—802
WOUNDS OF THE SPINAL CORD—Symptoms—In Lumbar and Lower Dorsal Region—In Upper Dorsal Region—In Lower Cervical Region—Above Phrenic Nerves—Partial Division	802—806
FRACTURE AND FRACTURE-DISLOCATION OF THE SPINE—Signs and Symptoms—Prognosis—Treatment.—DISLOCATIONS—Of Occipital Bone from Atlas—Of Atlas from Axis—Of any one of the Five Lower Cervical Vertebrae—Causes—Of Transverse Processes of Cervical Vertebrae—Wound of the Theca Vertebralis—Operation in Injuries of the Spine	806—815

CHAPTER XXVI.—INJURIES OF THE FACE AND ADJACENT PARTS.

FACE—Cuts of Cheek and Forehead—Lips—Parotid Duct—Salivary Fistula—Foreign Bodies in Nose.—EARS—Wounds—Foreign Bodies.—ORBIT—Dangers of Injuries of.—EYE—Injuries of the Conjunctiva—Of Eyeball—Contusions of the Eyeball—Rupture of the Globe—Wounds, Penetrating and Non-Penetrating—Sympathetic Ophthalmia.—Excision of Eyeball.—MOUTH.—TONGUE.—PALATE AND PHARYNX	816—825
---	---------

CHAPTER XXVII.—INJURIES OF THE THROAT : ASPHYXIA.

	PAGE
INJURIES OF THE LARYNX AND TRACHEA—Fracture of the Cartilages of the Larynx—Wounds of Throat—Not extending into Air- or Food-passages—Implicating Air-Passage—Effects—Treatment—Aerial Fistula—Foreign Bodies in Air-passage—Symptoms—Prognosis—Treatment—Scalds of Mouth, Pharynx, and Glottis—Treatment	826—838
ASPHYXIA—Causes—From Drowning—Artificial Respiration—Inflation of Lungs with Oxygen Gas—Secondary Asphyxia—From Noxious Gases—From Hanging	838—844
INJURIES OF THE PHARYNX AND OESOPHAGUS—Wounds—Rupture—Foreign Bodies—Symptoms—Treatment—Pharyngotomy or Oesophagotomy—Gastrotomy	844—847

CHAPTER XXVIII.—INJURIES OF THE CHEST.

WOUNDS OF THE CHEST-WALLS	848
FRACTURES OF BONES OF THE CHEST—Fracture of the Ribs and Costal Cartilages—Symptoms—Treatment—Gunshot Injuries—Fracture of Sternum—Treatment	848—851
INJURIES OF THE LUNG—Contusion—Rupture—Wound—Symptoms—Complications—Hæmorrhage—Hæmothorax—Emphysema and Pneumothorax—Pneumonia—Pleurisy and Empyema—Collapse of Lung—Subcutaneous Wounds of Lung from Fractured Ribs—Penetrating Wounds of Thorax with Wound of the Lung—Prognosis in Wounds of the Lung—Treatment—Treatment of Complications—Hernia of Lung, or Pneumocèle	851—865
WOUNDS OF THE HEART AND LARGE VESSELS—Wounds of the Pericardium—Laceration of the Pericardium—Wounds of the Heart—Symptoms—Rupture of the Heart from External Violence—Wounds of the Aorta and Vena Cava—Wound of the Thoracic Duct	865—869

CHAPTER XXIX.—INJURIES OF THE ABDOMEN AND PELVIS.

INJURIES OF THE ABDOMEN AND ABDOMINAL VISCERA—Contusions of the Abdominal Wall—Contusions of the Abdomen with Injury of some of the Viscera—Emphysema of Abdominal Wall—Wounds of Diaphragm—Wounds of Abdominal Wall—Non-penetrating—Penetrating: without Visceral Protrusion—with Visceral Protrusion—Wounds of Intestine—Treatment—Prognosis of Penetrating Wounds of Abdomen—Treatment—Sutures—Wounds of the Kidney—Rupture of the Uterus—Cysts in the Abdomen after Injury—Traumatic Peritonitis—Localised—Diffuse—Symptoms of Localised and Diffuse Peritonitis—Treatment of Traumatic Peritonitis	870—892
INJURIES OF THE PELVIC VISCERA—Rupture of Bladder—Symptoms—Treatment—Foreign Bodies in Bladder—Wounds of Organs of Generation—Wound of Urethra—Laceration of Urethra—Treatment—Foreign Bodies in Vagina and Rectum—Laceration of the Perineum—Operations for Rupture of the Perineum: Immediate—Remote	892—900

DIVISION THIRD.

SURGICAL DISEASES.

CHAPTER XXX.—MORTIFICATION, OR GANGRENE.

	PAGE
GANGRENE DEFINED —Local Signs—Constitutional Symptoms—Causes—Gangrene from Arrest of Supply of Arterial Blood—Ligature or Wound of Artery—Senile Gangrene—Mummification—Thrombosis of an Artery—Embolism—Gangrene from Venous Obstruction—from Arrest of Circulation by Strangulation—As a Termination of Inflammation—Arrest of Gangrene—Lines of Demarcation and Separation—Diagnosis—Prognosis—Treatment: Constitutional—Local—Amputation in Gangrene	901—917
BED-SORES —Treatment	917—918
BOILS —Definition of a Boil or Furuncle—Causes—Treatment	918—920
CARBUNCLE —Signs—Constitutional Disturbance—Causes—Diagnosis—Prognosis—Treatment—Facial Carbuncle—Diagnosis—Treatment	920—924
CANCORUM ORIS, OR NOMA —Symptoms—Pathology—Treatment	924
NOMA OF THE VULVA — GANGRENOUS VULVITIS	925

CHAPTER XXXI.—DISEASES ARISING FROM SEPTIC AND INFECTIVE PROCESSES IN WOUNDS.

General Remarks on Septic and Infective Processes—The Germ Theory	926—931
LOCAL INFECTIVE PROCESSES IN WOUNDS: WOUND-DIPHTHERIA —Causes—Treatment	931—932
HOSPITAL GANGRENE —Local Signs—Constitutional Symptoms—Causes—Pathological Anatomy—Treatment: Preventive—Local—Constitutional	932—936
SPREADING TRAUMATIC OR EMPHYSEMATOUS GANGRENE —Causes—Symptoms—Treatment	936—938

CHAPTER XXXII.—ERYSIPELAS. CELLULITIS. WHITLOW.

ERYSIPELAS —Characters—Erysipelatous Inflammation—Causes: Essential—Predisposing: Local and Constitutional	939—944
EXTERNAL ERYSIPELATOUS INFLAMMATIONS—CUTANEOUS —Local Symptoms—Constitutional Symptoms—Pathology—Diagnosis—Prognosis—Treatment: Preventive and Curative.— CELLULO-CUTANEOUS —Symptoms—Diagnosis—Prognosis—Pathology—Treatment.— CELLULAR —Local Signs—Pathology—Prognosis—Diagnosis—Treatment.— SPECIAL FORMS —In Newly-born Infants—Idiopathic Erysipelas of Head—Cellulitis of Orbit—Diffuse Cellulitis of Submaxillary Region—Erysipelas of Scrotum—Pudenda—Diffuse Cellulitis of the Ischio-rectal Fossa	944—958
INTERNAL ERYSIPELATOUS INFLAMMATIONS —Erysipelas of Mucous Surfaces—Fauces—Erysipelatous Laryngitis—Of Serous Membranes	958—960
WHITLOW, PARONYCHIA OR PANARITIUM .—Definition—Forms:—Paronychia Ungualis—Paronychia Cellulosa—Paronychia Osseosa—Paronychia Tendinosa—Treatment—Senile Teno-Synovitis	960—964

CHAPTER XXXIII.—SEPTICÆMIA AND PYÆMIA. TETANUS.

SEPTICÆMIA AND PYÆMIA—Definitions—Experimental Investigations—Causes	PAGE
	965—971
SEPTICÆMIA—Symptoms— <i>Post-mortem</i> Appearances—Diagnosis—Prognosis—Treatment.—SEPTIC INFECTION—Symptoms—Diagnosis—Prognosis—Treatment	971—974
PYÆMIA—Definition—Symptoms—Formation of numerous Centres of Inflammation and Suppuration— <i>Post-mortem</i> Appearances—Secondary Centres of Inflammation—Heart—Lungs—Liver—Spleen—Kidneys—Intestines—Joints—Microscopic Appearances of Tissues and Organs—Microscopic Organisms—General Pathology—Varieties of Pyæmia: Acute—Chronic—Umbilical—Without an Open Wound—Idiopathic—Mixed Forms of Pyæmia and Septicæmia—Prognosis—Diagnosis: from Inflammatory and Typhoid Fevers, from Ague, from Rheumatism, from Septic Poisoning and Septic Infection—Treatment: Preventive and Curative	975—989
TETANUS—Causes: Essential—Predisposing—Idiopathic Tetanus—Period of Occurrence—Symptoms—Varieties—Pathology— <i>Post-mortem</i> Appearances—Treatment	989—997

CHAPTER XXXIV.—TUMOURS.

DEFINITION—Classification—Non-Malignant, Benign, or Innocent Tumours—Malignant Tumours—Signs of Malignancy—General Characters of Typical Tissues: Connective—Embryonic—Epithelium—Classes of Tumours—Etiology of Tumours	998—1004
CYSTIC TUMOURS—Classification—CYSTS ARISING FROM DISTENSION OF PRE-EXISTING SPACES—Exudation-Cysts—Retention-Cysts—Atheromatous Cysts—Mucous Cysts—Cysts arising from Dilatation of Ducts of Glands—CYSTS OF NEW FORMATION—Simple or Serous—Hæmatoma or Blood-Cyst—Cystic Tumours—Cysts in Tumours—CONGENITAL CYSTS—Dermoid Cysts—In Imperfectly Organized Fœtal Structures—Teratoma.—PARASITIC CYSTS	1004—1016
TUMOURS COMPOSED OF ONE OF THE MODIFICATIONS OF FULLY DEVELOPED CONNECTIVE TISSUE—Fatty Tumour or Lipoma—Fibroma—Soft Fibromata—Wens—Molluscum Fibrosum—Fibro-cellular Tumours—Firm Fibromata—Fibromata of Bone—Of Nerves—Of Glands—Painful Subcutaneous Tubercle—Euchondroma, Chondroma, or Cartilaginous Tumours—Osteoma, Exostosis, or Bony Tumour—Myxoma, or Mucous Tumour	1016—1027
TUMOURS WHICH RESEMBLE IN STRUCTURE, MORE OR LESS PERFECTLY, ONE OF THE MORE COMPLEX TISSUES OF THE BODY—Myoma, or Muscular Tumour—Fibromyoma of the Uterus—Neuroma, or Nervous Tumour—Angioma, or Vascular Tumour—Lymphangioma, composed of Lymphatic Vessels—Lymphadenoma, composed of Lymphatic Tissue—Papilloma, resembling Papillæ of Skin or Mucous Membrane—Corns—Warts—Condylomata and Mucous Tubercles—Polypi—Vinous Tumours of Bladder—Adenoma, or Glandular Tumour—Tubular Adenomata—Racemose or Acinous Adenomata	1027—1035
TUMOURS COMPOSED OF TISSUE WHICH IS EITHER PURELY EMBRYONIC, OR IS UNDERGOING ONE OF THE PRIMARY MODIFICATIONS SEEN IN THE DEVELOPMENT OF ADULT CONNECTIVE TISSUE: SARCOMATA—Definition—General Character—Varieties—Small Round-Celled Sarcoma—Glioma—Spindle-Cellled Sarcoma—Oval-Cellled Sarcoma—Myeloid or Giant-Cellled Sarcoma—Ossifying and Ossified Sarcomata—Chondrifying Sarcoma or Chondro-sarcoma—Alveolar or Large Round-Cellled Sarcoma—Plexiform Sarcoma or Cylindroma—Melanotic Sarcoma—Psammoma—Sarcomatous Blood-Cysts or Hæmatomata—Mixed Sarcomata	1035—1046

TUMOURS COMPOSED OF CELLS OF AN EPITHELIAL TYPE, ARRANGED IN SPACES IN A STROMA CONSISTING OF MORE OR LESS PERFECTLY DEVELOPED FIBROUS TISSUE—	
Carcinomata—Varieties—Secondary Carcinomatous Growths—Clinical History—Causes: Constitutional—Exciting—Geographical Distribution—Constitutional or Local Origin—Theories of.—	
GLANDULAR— Scirrhus—Structure—Encephaloid—Structure—Colloid, Gelatinous, Gelatiniform or Alveolar—Diagnosis of Glandular Carcinoma.—	
SQUAMOUS CARCINOMA OR EPITHELIOMA— Causes and Situation—Progress—Structure—Diagnosis—Prognosis—Recurrence after Removal.—	
COLUMNAR CARCINOMA OR COLUMNAR EPITHELIOMA— Appearance and Progress—Structure—Diagnosis—Prognosis—Other Forms of Cancer—Treatment of Cancer—Constitutional Means Useless—Local Means—	
Palliative—Curative—Caustics—Compression—Excision—Question of Operating—Cases not Admitting Operation—Doubtful Cases—Cases Proper for Operation	1047—1082
EXCISION OF TUMOURS— Removal by the Knife—By the Écraseur—By the Cautey	
—By Ligature	1082—1085

CHAPTER XXXV.—TUBERCULOSIS. ACTINOMYCOSIS.

TUBERCULOSIS— Definition—Microscopic Characters of Tuberculous Tissue—Caseation of Tubercle—Extension of Tubercle—Naked-eye Appearances—Tuberculous Abscess and Ulcer—Constitutional Symptoms of Tuberculous Diseases—Constitutional Predisposing Causes: SCROFULA— Signs of the Scrofulous Diathesis—Local Predisposing Causes—Senile Tuberculosis—Treatment of Tuberculosis: Preventive—Curative—Tuberculin—Local Treatment of Scrofulous Affections—Operations in Scrofulous and Tuberculous Cases	1086—1104
ACTINOMYCOSIS— Definition—Pathology—Symptoms in Animals and in Man—Diagnosis—Treatment	1104—1106

CHAPTER XXXVI.—VENEREAL DISEASES.

DEFINITION AND CLASSIFICATION	1107
LOCAL CONTAGIOUS ULCER OR CHANCERE— Characters—Origin and Progress—Varieties—Simple or Soft—Sloughing Chancre—Phagedenic—Situation of Chancre—Diagnosis—Local Treatment of Chancre—Of Sloughing Chancre—Of Phagedenic Chancre—Constitutional Treatment of Simple Chancre—Of Sloughing Chancre—Of Phagedenic Chancre—	
CONSECUTIVE SYMPTOMS OF THE LOCAL CONTAGIOUS ULCER— Contracted Cicatrices—Bubo—Primary Bubo—Creeping Bubo—Treatment—Venereal Warts	1107—1119
SYPHILIS— Characters—Period of Incubation—Primary, Secondary, and Tertiary—Origin—Contagion of Syphilis—Transmissibility—Duration of Transmissive Power—Progress—Period of Incubation—Appearance of Primary Sore—Indurated or Hunterian Chancre—Seat and Number—Urethral Chancre—Labial and Facial Chancres—On Tongue—On Fingers—Variations in Sore—Prognosis—Course—Indolent Enlargement of Lymphatic Glands—Enlargement of Dorsal Lymphatics of Penis	1119—1130
SECONDARY AND TERTIARY CONSTITUTIONAL MANIFESTATIONS OF SYPHILIS— General Pathology and Progress—Microscopy of Gummata—Prognosis—Duration of Syphilis—Treatment of Primary Stage: Local and Constitutional—Administration of Mercury—Other Drugs	1130—114

CONTENTS.

xxi

	PAGE
LOCAL SECONDARY AND TERTIARY MANIFESTATIONS OF SYPHILIS —Syphilitic Affections of the Skin—Mucous Tubercles and Condylomata—Syphilis of Mucous Membranes—Syphilitic Iritis—Syphilitic Diseases of the Bones—Syphilitic Necrosis and Caries—Syphilitic Tumours of Muscles and Tendons—Syphilitic Disease of Testicle—Syphilitic Ovaritis—Visceral Syphilis—Syphilitic Disease of the Mamms—Of the Nervous System—Of the Spinal Cord	1147—1165
INFANTILE, CONGENITAL, OR INHERITED SYPHILIS —Nature—Symptoms—Influence on Teeth—On Bones—Chronic Interstitial Keratitis—Chronic Affections of Ear—Affections of Viscera—Of Testicles—Evidence of Congenital Syphilis in Later Childhood or Adult Life—Prognosis—Treatment	1165—1173

INDEX TO VOLUME I.	1175
-------------------------------------	------

LIST OF ILLUSTRATIONS TO VOL. I.

FIG.		PAGE	FIG.		PAGE
1	Clover's Ether Inhaler	21	38	Result after Amputation of Ring Finger	97
2	Junker's Chloroform Inhaler	26	39	Amputation of Right Thumb and Metacarpal Bone	98
3	Bistoury held perpendicularly	41	40	Result after Amputation of Thumb and its Metacarpal Bone	99
4	Scalpel held like a Pen	42	41	Hand after Amputation of First Two Fingers and Metacarpal Bones	100
5	" " Dinner-knife	42	42	Hand after Removal of Three Fingers and Metacarpal Bones	100
6	Division of Fascia on a Director	43	43	Amputation at Wrist : Dorsal Flap	100
7	Dissection through a Fascia	44	44	" " Palmar Flap	101
8	Esmarch's Tourniquet on Shoulder	46	45	Amputation of Forearm : Transfixion	103
9	" " " Thigh	47	46	" " " Skin Flaps	104
10	" " " round Hip	47	47	" " Arm : Clearing Bone	105
11	" " " Penis	47	48	" " at Shoulder : Outer Flap	106
12	Lister's Bloodless Method	48	49	" " " Inner Flap	107
13	Esmarch's " " "	49	50	" " " Holding Vessels	108
14	Compression of the Carotid	50	51	" " " Spence's Method	109
15	" " " Facial, Temporal, and Subclavian Arteries	50	52	" " " Stump after	110
16	Compression of Subclavian with Key, and of Brachial with Fingers	51	53	Amputation of a Toe	113
17	Compression of Radial and Ulnar	51	54	Amputation of Great Toe by Racket-shaped Incision	114
18	Lister's Aorta Compressor	52	55	Flap Amputation of Great Toe	115
19	Digital Compression of Femoral—Petit's Tourniquet on Thigh	53	56	Amputation of Little Toe by Racket-shaped Incision	115
20	Compression of Tibials	53	57	Lines of Hey's and Chopart's Amputations	117
21	Circular Amputation : First Incision	60	58	Chopart's Amputation : Sole Flap cut first	117
22	" " " Sawing the Bone	61	59	Lines of Incision in Operations on Foot	118
23	Flap Amputation : by Transfixion	63	60	Chopart's Amputation : Disarticulation first	118
24	Modified Circular Amputation	68	61	Subastragalar Amputation	120
25	Teale's Amputation : Lines of Incision	69	62	Lines of Incision : Syme's Amputation	121
26	Teale's Amputation : Stump	69	63	Lines of Incision : Syme's and Pirogoff's Amputations	121
27	A Stump : Mode of applying Sutures and Drainage-tube	74	64	Syme's Amputation : Cutting Flap	122
28	Ends of Nerves in a Stump	76	65	" " " Disarticulation	122
29	Sequestrum of Femur from Stump	77	66	Pirogoff's Amputation : Line of Incision	123
30	Extreme case of Conical Stump	77	67	Pirogoff's Amputation : Sawing Os Calcis	124
31	Aneurismal Varix in Stump	78	68	Pirogoff's Amputation : after Removal of Malleoli	125
32	Amputation of Ungual Phalanx	94			
33	" " " Middle "	94			
34	" " " Whole Finger	95			
35	" " " Index Finger	96			
36	Result after Amputation of Middle Finger	97			
37	Result after Amputation of Index Finger	97

69 Pirogoff's Amputation : Stump after	125	106 Rifle Bullets	346
70 Amputation of Leg : Transfixion of Posterior Flap	127	107 Gunshot wound : Aperture of Entry	347
71 Amputation of Leg : Sawing Bones	128	108 " " " Exit	347
72 Amputation of Leg : Teale's	128	109 " " " Temporary Tour- niquet	353
73 " " " Skin Flaps	130	110 Round Bullet in Head of Humerus	363
74 Amputation through Knee	132	111 Gunshot Fracture of Humerus (U.S. Army Med. Dep.)	364
75 " " " Lateral Flaps	133	112 Result of Excision of Head and Six Inches of Shaft of Humerus	364
76 Amputation through Condyles : Lis- ter's	134	113 Bacillus Anthracis in Lung	382
77 Amputation of Lower Third of Thigh : Lateral Flaps	136	114 Cicatrix of Lip and Neck after Burn	399
78 Amputation of Thigh : Flaps cut from Without	138	115 Contraction of Elbow from Burn	399
79 Fournier's Jordan's Amputation at the Hip-joint	140	116 Dislocation of Little Finger back- wards from Burn	399
80 Amputation at the Hip-joint : For- mation of Anterior Flap in Left Limb	141	117 Deformity of Left Hand after Burn	399
81 Amputation at the Hip-joint : For- mation of Anterior Flap in Right Limb	142	118 Deformity of Foot from Burn	400
82 Amputation at the Hip-joint : Com- pression of Femoral	143	119 Teale's Operation for Restoration of Lip	401
83 Lanza of Incision for Amputation at Hip	145	120 Teale's Operation : Flaps in Place	401
84 Migration of Leucocytes from Vein	160	121 Completely Ruptured Artery	408
85 Inflamed Fat	168	122 Apparatus for Intravenous Injection of Saline Fluid	412
86 Sluggishly Inflamed Fascia	169	123 Introduction of Cannula into Vein	412
87 Introduction of a Seton	233	124 End of Cauterized Artery	422
88 Microscopic Abscess in Skin	230	125 Torsion of Brachial	425
89 Pus from Acute Abscess, before and after Treatment with Acetic Acid	242	126 Torsion Forceps	426
90 Pus from Acute Abscess, containing the Staphylococcus pyogenes	243	127 End of Twisted Femoral	426
91 Pus containing the Streptococcus pyogenes	244	128 Forei-pressure Forceps	428
92 Fracture Chronic Abscess	253	129 Ligature of Artery	429
93 Large Psoas Abscess	254	130 Liston's Bull-dog Forceps	430
94 Aspirator	258	131 The Ligature Knot	430
95 Serris Forceps	262	132 Opening the Sheath of an Artery	433
96 Sharp Spoon	265	133 Cleaning an Artery	433
97 Granulation Tissue : Section through	289	134 Passing an Aneurism Needle : 1st Stage	434
98 Young Cicatrix : Section through	290	135 Passing an Aneurism Needle : 2nd Stage	434
99 Granulating Sore, injected : Section	294	136 Artery : Immediate Effects of Liga- ture	435
100 Finger Torn Off, with Tendon	335	137 Femoral Artery : 56 hours after Am- putation	435
101 Thumb Torn Off	335	138 Ligatured Artery laid open	436
102 Arrow penetrating Skull (Army Med. Dep. U.S.A.)	342	139 Femoral Artery, 5 weeks after Am- putation	436
103 Bullet wound pierced by Arrow (Army Med. Dep., U.S.A.)	343	140 Femoral Artery, 14 days after Am- putation : Partial absorption of coagulum	436
104 Hare's Scare for extraction of Arrow- heads	343	141 Absorption of Catgut Ligature : Sec- tion	441
105 Splitting of Femur by Bullet (Army Dep., U.S.A.)	346	142 Acupressure : 1st Method, Raw Sur- face	445
		143 Acupressure : 1st Method, Skin Sur- face	445
		144 Acupressure : 2nd Method	445
		145 " " 3rd "	445

DIVISION FIRST.

FIRST PRINCIPLES.

CHAPTER I.

GENERAL CONSIDERATIONS ON OPERATIONS.

A **SURGICAL OPERATION** is a Mechanical Procedure undertaken for the remedy of Deformity, congenital or acquired, or for the relief of those effects of Injury or Disease that are not curable by constitutional or ordinary local treatment, or in which such treatment would be too slow in effecting the desired result.

A *Surgical Operation* may be necessary for the following objects :

1. *Remedying or Removing Congenital Defects and Malformations* : as Hare-lip, Club-foot, or Supernumerary Fingers or Toes.

2. *Remedying Acquired Defects and Deformities* : as in the Closure of Fistulae, the Restoration of Lost Parts, and the Correction of Distortions of the Limbs.

3. *The Removal of Foreign Substances* from the Body : as in the Extraction of a Bullet or a Calculus.

4. *The Repair of the Effects of Injuries* : as in the treatment of certain Fractures and Dislocations.

5. *The Removal of Parts* that have been so disorganised by the effects of *Injury* that their continued connection with the rest of the body would be a source of danger : as in Amputation for Frost-bite or Mangled Limbs.

6. *The Removal of Diseased Structures* that interfere with the utility of an organ or part : as in the Extraction of a Cataract.

7. *The Removal of Diseased Structures* that seriously inconvenience the patient or that remotely threaten life : as in the Extirpation of Tumours, simple or Malignant.

8. *Rescuing a Patient from Immediate and Inevitable Death* : as in Tying a Bleeding Artery, Opening the Windpipe in Laryngeal Obstructions, Relieving an Over-distended Bladder, or Dividing the Stricture in Strangulated Hernia.

Operative Surgery, like every other art, can be carried only to a certain point of excellence. An art may be modified—it may be improved—but it cannot be perfected beyond certain limits. And so it is, and indeed must be,

with that of Surgery. There cannot always be fresh fields for conquest by the knife. There must be portions of the human frame that will ever remain sacred from its intrusion—at least, in the Surgeon's hand.

When we reflect that every large artery in the body up to the aorta itself has been ligatured, that each of the six large articulations and many of the bones have been resected, that amputation at the shoulder or hip is a matter of ordinary occurrence, that tumours have been excised from every region of the body, that the larynx, the spleen, the kidney, the pregnant uterus, and even portions of the liver, stomach and brain have been successfully removed, we can scarcely doubt that the limits of Surgery have been nearly reached. It is possible that they may even have been occasionally exceeded, for some of the operations recently performed for the removal of important organs have been far from successful, and it has yet to be determined whether they are surgical triumphs or mere operative audacities. The Surgeon of the future can scarcely hope to invent new operations; he must be content to modify and perfect those that have been devised by the genius and skill of his predecessors.

But if the mechanical Art of Surgery has attained to so high a degree of perfection that we can scarcely hope for much further progress in that direction, the case is widely different with the Science. Here truly, so far from having approached the limits of our subject, we are but as yet on the threshold. For whether we regard the science of Surgery in its relation to the essential nature, the pathology and the diagnosis of surgical diseases and injuries, or whether we consider it in reference to all those circumstances which, independently of the mechanical skill of the operator, influence for good or for ill the results of his procedures, we have a field before us the extent of which it is difficult yet to estimate.

Until a comparatively recent period, although the results of minor operations were generally satisfactory, the success attending those graver procedures, by which the life of the patient is directly imperilled, bore no relation to the perfection in the execution of the operation. At this time the highly polished Art of Surgery far outshone its Science. The rapid advance of scientific knowledge, however, during the last quarter of a century, has not been without its influence on the Art of Surgery. The history of Surgery is characterised by great discoveries, forming landmarks which stand out prominently as starting-points from which new departures have been taken in its Art. Such were the revival of the use of the ligature in the sixteenth century, the discovery of the circulation of the blood, the invention of the tourniquet in the seventeenth, and the introduction of the Hunterian operation for Aneurism in the eighteenth. The nineteenth century will ever be conspicuous as that in which the inestimable boon of Anæsthetics was conferred upon mankind; by means of them not only has pain in Surgery been abolished, but the extent of its operative department immensely enlarged, for they enable the Surgeon to perform, and the patient to undergo procedures, the agony of which would otherwise have been beyond the power of human endurance. Of no less importance has been the discovery of the relation of micro-organisms to putrefaction and to infective diseases. The so-called "germ-theory of putrefaction" was first established as a scientific truth by the researches of Pasteur, but it is undoubtedly to Lister that Surgery owes the application of this theory to practice. The scientific employment of antiseptics as introduced by

him, and modified subsequently by himself and numerous other Surgeons, has probably saved more lives than any single discovery since vaccination. However the details of the *Antiseptic Method* may be varied in the course of time, the principle which underlies it and on which its details are founded cannot change, for it is based upon facts now beyond dispute. The principle may be briefly described as follows. The vast majority of unhealthy inflammations in wounds and the constitutional affections which arise from them, are due to the presence of microscopic organisms which have gained admission directly from without. These organisms may enter the wound from the air, but are more commonly carried by water, or by the Surgeon's hands or instruments. Experimental investigation has shown that they are destroyed by numerous chemical substances known as antiseptics. The antiseptic method of treatment consists, therefore, in preventing the entrance of these organisms by the use of antiseptic solutions, for washing the wound, or sponges; in disinfecting with similar solutions all instruments and the Surgeon's hands, and the wound itself, if it have been exposed to infection, as must necessarily be the case in all accidental injuries. The wound being thus freed from all living organisms, is protected from subsequent infection by the application of a dressing impregnated with some antiseptic substance. It is an important feature of the Antiseptic Method, that after the wound has been once disinfected, the antiseptic shall not be allowed to come in contact with the raw surface, as all chemical antiseptics are more or less powerfully irritating. This distinguishes the true Antiseptic Method from the old-fashioned plan of using disinfectants. The object of the Antiseptic Method is absolutely to prevent putrefaction or infection, and at the same time to irritate the raw surfaces of the wound as little as possible by the antiseptic. In every detail of practice the Surgeon must be guided by the theory. Antiseptics have been used in Surgery from time immemorial, but the results obtained were unsatisfactory till their employment was directed by more accurate knowledge of the causes of putrefaction and of infection. Their scientific use has revolutionised modern Surgery, and has done almost as much to extend the field of operative surgery as the introduction of Anæsthetics.

A scarcely less noticeable feature of this epoch has been the application of the rules of hygiene to the construction and management of hospitals, by which the general health of the patients has been much benefited and the mortality reduced.

Success in the results is, after all, the thing to aim at, and no amount of manual dexterity can compensate for its want. Manual dexterity is necessarily of the first advantage in the performance of any operation, and the Surgeon should diligently endeavour to acquire the art of using his instruments with readiness and certainty; but it would be a fatal error to suppose that this is the only or indeed the chief requirement on the part of an operator. Manual dexterity must not be mistaken for surgical skill; and, desirable as it may be to be able to remove a limb, or to cut out a stone, with rapidity,—important, in a word, as it is to become a dexterous operator—it is of far greater importance to become a successful Surgeon. The object of every operation is the removal of some condition that either threatens life, or interferes with the comfort or utility of existence; and the more safely as well as certainly a Surgeon can accomplish this object, the better will he do his duty to his patients, and the more successful will he be in his practice. Success then, in

the result of an operation is the thing to aim at, and to this, dexterity and rapidity in operating are in a high degree conducive; but the Surgeon must also be prepared to deal with complex problems, the solution of which can only be afforded by an intimate general acquaintance with the Science of Surgery and of Medicine. The Diagnosis of the local disease, and of the extent of its connections, must be made; lurking visceral affections must be detected and, if possible, removed. The Constitution of the patient must be prepared: he must, as far as possible, be placed in those hygienic conditions which are most favourable to recovery; the best time for the performance of the operation must be seized; and, after its completion, the general health must be attended to in such a way as shall best carry the patient through the difficulties he has to encounter, and any sequelæ or complications that arise must be subjected to appropriate treatment. These, as well as the simple performance of the operation, are the duties of the Surgeon; and on the manner in which they are performed, as much as, or perhaps even more than, on the mere manual dexterity displayed in the operation itself, will the fate of the patient depend. Success in Operative Surgery mainly depends on two conditions: 1. The selection of proper cases; that is to say, of cases in which alone an operation will probably be followed by a successful result; and 2. the avoidance or the combating of those deleterious influences, hygienic and others, to which a patient may be exposed after an operation, and which may directly mar its success.

The practice of operating in notoriously hopeless cases, with the view of giving the patient what is called a "last chance," is much to be deprecated. By operating in such circumstances, especially in malignant diseases, much discredit has resulted to Surgery; for in a great number of instances the patient's death is hastened by the procedure, which, instead of giving him a last chance, causes him only to be despatched sooner than he would otherwise have been.

It may truly be said that a great surgical operation, in its conception, its performance, and its completion, tests the Surgeon's medical knowledge as much and in as varied a manner as it taxes his manual skill; and that, taken as a whole, it is the highest development of the medical art.

CONDITIONS INFLUENCING THE SUCCESS OF OPERATIONS.

The circumstances that mainly influence the result of an operation, so far as the recovery of the patient is concerned, may be arranged under three heads:—1. Those that are connected with the *State of the Patient's General Health* before and at the time of its performance; 2. The *Hygienic Conditions* by which he is surrounded after it is done; and 3. The *Special Dangers* connected with the operation itself.

1. All other circumstances being alike, the condition of a patient that principally determines the result of an operation is the **State of the General Health**. Sometimes we see a patient carried off by disease supervening on some trifling operation, (such as the removal of a small tumour,) which in itself ought in no way to endanger life, were it not that the patient's constitution was at the time of its performance in so unhealthy a state that the slightest exciting cause has been sufficient to call the fatal disease into activity. So, also, it is no uncommon experience to see one patient sink after an

operation most dexterously performed, owing to some constitutional condition that predisposes to diffuse inflammations; whilst another may possibly make the most remarkable and rapid recovery after he has been mutilated with but little skill. Independently of actual organic disease of the viscera, of which I shall hereafter speak, there are certain conditions of the nervous system, the circulation, and the general physical state that exercise an injurious influence. Thus, persons of an irritable and anxious mind do not bear operations so well as those of a more tranquil mental constitution. Those also of a feeble and irritable habit of body, especially nervous and hysterical women, with but little strength of circulation, cannot bear up against severe surgical procedures, and are apt to become depressed and to sink without rallying. Persons who are overloaded with fat are not good subjects for surgical operations. In them the circulation is usually feeble; the wound heals slowly, and is apt to slough; and general or local infective processes readily occur. Short of actual structural disease of important organs, as the lungs, heart, or kidneys, I know no condition more unfavourable to success after operations than premature or excessive obesity.

Operations on very old people, if severe and attended by much shock, are commonly fatal; amputations after the age of seventy are rarely successful.

Patients with a high temperature should never be operated on except for the relief of the condition causing the fever, such as the accumulation of pus, or rapidly spreading gangrenous inflammation, or in one of those four great surgical emergencies that under all circumstances demand immediate operation: viz: 1, dangerous hæmorrhage; 2, impending asphyxia; 3, strangulated hernia and intestinal obstruction; and 4, over-distended bladder. The urgency of these conditions, which may be termed the four classes of primary surgical urgency, overrides all other considerations.

An individual with a constitution unimpaired by excesses of any kind, whose habits have been temperate, whose diet has been sufficient and of good quality, whose mind has never been over-strained by the anxieties of business or the labours of a professional life, and whose existence has been spent in rural occupations and in the pure air of the country, is necessarily placed in a far more favourable position to bear the effects of any mutilation, whether it be the result of accident, or inflicted by the Surgeon's knife, than the man whose physical powers are worn out by active and unceasing business avocations or professional work, whose nervous system is exhausted by his anxious labours; and infinitely more so than the poor inhabitant of a large and densely peopled town, who has from earliest childhood inhaled an impure and fetid atmosphere, whose scanty diet has consisted of the refuse of the shops, or the semi-decomposed offal of the stalls, and whose nervous system has been irritated and at the same time exhausted in the daily struggle for a precarious livelihood, or over-stimulated by habitual excesses in strong drinks. Though individuals with such different antecedents be placed under exactly the same hygienic circumstances *after* the performance of an operation, yet the results will probably be very dissimilar, influenced as they must be by their past rather than by their present condition.

Besides the general state of the patient's health, the *Condition of Important Organs* must be taken into consideration before an operation is decided on. The state of the *Heart* should be carefully looked to. Valvular disease, if early or slight, need not be an obstacle to most operations, even to those of

expediency: but fatty degeneration, as indicated by its feeble action, by irregularity and want of power in the pulse, by breathlessness, and by a distinctly marked arcus senilis, should make the Surgeon cautious about undertaking any operation attended with much loss of blood or shock. Such a condition of heart is liable to occasion great depression of strength, syncope, and death—often sudden—some days after the operation. In cases of chronic disease that it would otherwise be proper to submit to operation, this condition of the heart becomes a serious obstacle, but it need not be a bar to operation in acute cases that would be speedily fatal if left to themselves, and certainly not in one of the four conditions of primary surgical urgency.

Tubercular Disease of the *Lungs*, when active or advanced, is prejudicial to the success of an operation: but under certain circumstances, as will be explained when speaking of diseases of the joints and fistula in ano, an operation is justifiable, even though the patient be consumptive.

If the *Liver* be affected by cirrhosis, and more especially if any symptoms of ascites have supervened, no operation but for the relief of disease that instantly threatens life should be undertaken. Amyloid degeneration does not counter-indicate an operation if, by that means the cause of the condition can be removed, as in some cases of chronic joint or bone disease.

Perhaps, however, the affection that militates more than any other against the success of an operation, is disease of the *Kidneys*, with albuminuria: in this condition the local inflammation that is set up is apt to assume a diffuse and sloughing form, and this is especially the case in all operations about the pelvic and genito-urinary organs.

Saccharine Diabetes is another condition which seriously endangers the success of any operation. In acute diabetes no operation should ever be undertaken but for the immediate preservation of life. The tendency to the occurrence of carbuncle and spontaneous gangrene is a well-known feature of the disease, and this shows itself after an operation by want of repair, or sloughing of the surfaces of the wound. The feeble tissues readily become infected by septic organisms, which set up widely-spreading diffuse inflammation followed by septicaemia and death.

In chronic diabetes of middle life, when the patient is well nourished and often gouty, operations may be undertaken with a fair prospect of success. The conditions indicating the possibility of operating are, first, the amount of sugar should not exceed 2 per cent., and should be easily reducible below this by the administration of opium and proper diet: secondly, the general symptoms, thirst, hunger, loss of flesh, &c., must not be marked, and the "knee-jerk," which is often lost in diabetes, should be present: and thirdly, the proposed operation must be one in which asepsis can be ensured with certainty. Even in such selected cases death will frequently follow a severe operation, either from exhaustion or from the supervention of coma. The patient should be kept gently under the influence of opium till the wound is healed, and the diet should, as far as possible, be that ordinarily employed in the treatment of diabetes, all starchy and saccharine matter being excluded. Should the wound become septic, the patient's chance of recovery is small, even from a comparatively slight operation.

Albuminuria and diabetes form, in fact, such serious complications, that no operation, even the most trivial, should be undertaken, except in cases of

emergency, without previously examining the urine both for albumen and sugar.

The contamination of the patient's system by *Malignant Disease* must always prevent our operating: as, if this has taken place, the disease cannot be completely removed. And, lastly, no operation, save for the purpose of rescuing the patient from impending death, should ever be performed whilst he is labouring under *Pyæmia*, *Septicæmia*, *Erysipelas*, *Phlebitis*, or any *Diffuse Inflammation*; and even during the epidemic prevalence of these affections, operations that are not of immediate necessity should be postponed until a more favourable season.

2. **The Hygienic Conditions** to which a patient is exposed both before and after an operation, will most materially influence its results. These conditions are of two kinds:—1. As regards the diet of the patient, and 2. As concerns his exposure to a vitiated atmosphere contaminated by the emanations from the sick and wounded, such as is commonly met with in the wards of an over-crowded or ill-constructed hospital.*

The proper regulation of the patient's *Diet* before and after an operation is of great consequence. On this point it is impossible to lay down any very definite rule, as much depends not only on the patient's previous habits of life, but on the nature of the operation itself: and, as this subject will be discussed at the end of the Chapter, it need not detain us here. It is not often, however, that in civil practice the insufficient quantity or the bad quality of the patient's food, with which he is supplied *after* the performance, influences materially the result of an operation. But in military and naval practice in time of war the case is far different. The soldier or the sailor on active service is often exposed to serious injuries that necessitate important operations at a time when he has already been weakened by scurvy, dysentery, or some similar affection, resulting from the deficient quantity and the unwholesome character of his food. After the operation his only available nutriment may be of the coarsest character, possibly salted, and imperfectly cooked. In such circumstances, and in the absence of efficient antiseptic treatment which must often be unavoidable in war, wounds do not heal, or they assume a peculiar gangrenous character; and the patient dies from septicæmia or pyæmia, or from profuse diarrhoea with ulceration of the intestines. The mortality of operations becomes enormously increased: and thousands of deaths which have occurred in wars between the most civilised nations and the best appointed armies have been due to these causes.

The *Hygienic Conditions* to which the patient is subjected after an operation will necessarily vary greatly according to the locality in and the circumstances under which it is performed—whether it is done in a private house, where the patient may be isolated, freed from the chance of all contamination, and surrounded by every sanitary precaution: or in a hospital, where he may be exposed to emanations, possibly of a septic and infectious character, from other patients, where the building may be impregnated by the exhalations from generations of sick and injured, and where sanitary measures may be neutralised by the conditions generated by a vast assemblage of sick under one roof. Then, again, the circumstances in which a patient is placed after an operation for an accident of civil life are necessarily very different from those

* I refer the reader who wishes to study this very important subject more deeply to my *Lectures on Hygiene and the Causes of Death after Operations*. (Longmans, 1874.)

that surround one who is exposed to the peculiar perils that are necessarily connected with military hospitals and ambulances in time of war, and which will be more fully described in the chapter on Gunshot wounds.

In private practice, ill results may follow operations from three different causes, viz. : self-infection of the patient, in consequence of the retention of decomposing secretions in the wound ; conveyance of infection by the Surgeon ; and general faulty sanitary arrangements. In hospital practice these different sources of danger must necessarily exist to the same if not to a greater extent than in private. In hospital, however, just as in private practice, these particular dangers are all preventable, and disease of a septic character ought not to be allowed to generate itself through their medium. The frequency of such an occurrence is in the direct ratio of the want of hygienic attention bestowed upon the patient.

The air of large towns in which the majority of hospitals must necessarily be situated is more or less loaded with impurities. The normal 4 parts per 1,000 of carbonic acid gas is always exceeded, the amount sometimes reaching as high as 5 or 55, and there is moreover always a deficiency, often a total absence, of ozone. The amount of solid impurity is also very considerable. It has long been known that the atmosphere of inhabited houses and cities is loaded with minute particles of organic matter in suspension. Forty years ago Pouchet demonstrated the presence of starch granules in the dust deposited in a room. In 1861 Pasteur proved that the spores of some of the higher fungi are always to be found in the air of Paris. Tyndall also demonstrated by numerous experiments that a large proportion of the dust of the air is composed of organic matter. Further, microscopic observations by Pouchet and others showed that the air of inhabited rooms contains in suspension scaly epithelium, fragments of human hair and of cotton, linen and wool from the clothing. In hospital wards dried pus cells have also been found. All these impurities may be recognised without difficulty by microscopic examination of dust collected from the air. The experiments of Pasteur, Tyndall, Lister, and many others, further conclusively proved that the air contains minute solid particles, which act as ferments on dead organic matter, giving rise to such processes as the ordinary putrefaction of albuminoid substances, the lactic acid fermentation of milk, &c. That these particles are organised bodies, minute fungi or their spores, is now universally acknowledged. The number and nature of these organisms has been made the subject of daily observation by Miquel in the Observatory of Montsouris in Paris for many years past, and many interesting facts have been ascertained. His method of observation consists in drawing a measured quantity of air through a glass bulb filled with a solution of Liebig's extract of beef, which forms a suitable cultivating medium for microscopic fungi of almost all kinds. The fluid is, of course, freed from all living organisms before the experiment by prolonged boiling. If, after the admission of air, microscopic organisms appear in the fluid, he assumes that the quantity drawn through contained at least one microscopic fungus or its spore. Another mode of investigation which, in the hands of Koch and others, has given results confirmatory of those obtained by Miquel, is to expose to the air for a fixed time a measured surface of properly prepared nutrient gelatine freed from organisms by heat. The single organisms or spores which fall on the gelatine soon develop into colonies visible to the naked eye, and by

counting these the number of organisms that have been deposited can be ascertained, and their nature may be determined by subsequent microscopic examination. The general results of these observations have been to show that the number of micro-organisms in the pure air of a mountain top is very small, in fact they may be absent. In the air of an ordinary country place they are scarce, but always present; in the air of a city they become numerous, and the atmosphere of a surgical ward is often loaded with them. Thus, in the Observatory of Montsouris, which is situated in a park on the outskirts of Paris, the daily average was 75 organisms per cubic metre; in the Rue de Rivoli it was 750; in the low parts of Paris 850, and in a ward in the hospital of La Pitie it amounted to 11,100. In the wards of the hospital the number rapidly increased, when, owing to cold weather, the windows were closed. It may therefore be taken as proved that the air of hospitals, and inhabited houses generally, contains floating in it numerous organisms which are capable of growing in the discharges of wounds, and of establishing in them various fermentative changes, the products of which are more or less detrimental to the patient both locally and constitutionally. It is by no means necessary that the fermentative process thus induced should be the ordinary fetid putrefaction; in fact the organisms which cause this are scarce in the air, being much more abundant in water; still, although there may be no smell, the fermentation set up in the discharges is not always innocuous.

The air of a surgical ward or sick room is vitiated by the patient, first, by the normal products of respiration and excretion from the lungs and skin; and secondly, in many cases by the emanations from wounds or sores. The first is unavoidable, the second is to a great extent under the control of the Surgeon.

An average adult man gives off per hour about 6 cubic feet of carbonic acid gas, from 1 to 1½ ounces of water, and an undetermined quantity of organic matter. This organic matter is partly solid, consisting of epithelium and fatty matter from the skin and mouth, and partly a vapour given off from the lungs, the nature of which is somewhat uncertain. It is extremely offensive, and is so imperfectly diffusible that it is probably in great part molecular; it is nitrogenous and oxidisable, although but slowly. It is readily absorbed by damp walls or bedding, the most hygroscopic substances taking it up most readily. It is this substance that gives the fusty smell to an ill-ventilated room. Experiments have shown that it is highly poisonous, and this explains the fact that air fouled by respiration is much more deleterious than that vitiated by combustion or by the addition of pure carbonic acid gas. Parkes states that "allowing the fullest effect to all other agencies, there is no doubt that the breathing the vitiated atmosphere of respiration has a most injurious effect on the health. Persons soon become pale, and partially lose their appetite, and after a time decline in muscular strength and spirits. The aeration and nutrition of the blood seem to be interfered with, and the general tone of the system falls below par." Under such circumstances convalescence is prolonged; the reparative power is less, wounds tend to slough, and the patient is more readily affected by any local or general infective process to the poison of which he may be exposed.

The special contamination of a surgical ward may arise, first, from the presence in the atmosphere of the gaseous products of decomposition; secondly, from a great abundance of the organic particles which act as the

ferments in decomposition : thirdly, from the presence of dried particles of the discharges from wounds or sores : and, lastly, by the contagia of specific infective processes, whether general or local.

The gaseous products of decomposition, consisting of sulphuretted hydrogen, sulphide of ammonium, free ammonia, carburetted hydrogen, carbonic acid, and many others undoubtedly tend to aggravate the symptoms produced by the accumulation of the products of respiration : but it is impossible to separate the effects produced by the former from those of the latter, with which they must almost necessarily be complicated in a hospital ward. Parkes states that the putrefying animal matter which frequently accumulates about camps during war forms one of the principal causes of diarrhoea and dysentery : but it is only in military practice in which large numbers of wounded must occasionally be packed closely together and their wounds neglected for want of sufficient surgical assistance, that putrid discharges could accumulate to such an extent as to develop these diseases.

Secondly, the air of a ward containing many foul wounds has been shown to contain a great excess of organic matter, but it is impossible to separate the effects produced by it from those of foul air generally.

Thirdly, microscopic examination has demonstrated the presence of dried pus cells in the air of surgical wards in addition to the epithelium always met with in inhabited rooms. It has been supposed by some that these might possibly act as the material of contagion ; that they may be the bearers of contagion cannot reasonably be doubted.

Lastly, the air of surgical wards is apt to be contaminated by the contagia of specific infective processes, such as hospital gangrene, erysipelas, pyæmia, &c. The exact nature of the contagium in all these diseases is not yet definitely ascertained. This much is certain, that the poison in all is particulate : it is never gaseous. Its activity can be destroyed by those chemical substances that we class as antiseptics. In the majority of cases the specific infective process commences in a wound, the discharges of which are in a putrid state ; and those methods of treatment which are best calculated to prevent putrefaction also serve best to prevent the occurrence of infective processes, either local or general. It may now be said to be practically proved that all these unhealthy spreading inflammations are accompanied by the presence of microscopic organisms in the discharges, and often in the lymph spaces near the wound : and the view is now universally accepted that these micro-organisms are directly or indirectly the cause of the unhealthy processes, and that infection is brought about by the actual transference of some of these living particles from one patient to another. In the human subject erysipelas has been definitively proved to be caused by the invasion of the lymph-spaces of the skin by a specific fungus. Koch has shown that diseases closely resembling gangrenous erysipelas, septic infection, and pyæmia, as they occur in the human subject, can be artificially produced in animals : that each disease is accompanied by the presence of a distinct form of micro-organism, and that it can be transmitted from one animal to another by means of infinitesimal quantities of the blood or exudation fluids containing the characteristic organism. That the organisms or their spores retain their vitality after being dried has been clearly proved with regard to the somewhat analogous disease of anthrax in cattle. This disease is due to a rod-shaped organism, the *bacillus anthracis*, of such size that its life-

history can be accurately studied. It has been found that under certain conditions minute spores are developed in the bacillus, and that when this has taken place blood containing the virus may be dried and kept in that state for years without losing its virulence. In this state it is easily conceivable that it could be disseminated by the air. It is well known that the virus of variola, small-pox, and scarlet fever equally resist the effects of drying.

Another fact of equal importance, which was first discovered by Pasteur and Toussaint, is that the virus of splenic fever and that of a peculiar form of septicæmia, common in fowls, known as chicken cholera, lose considerably in virulence if the organisms which form their essential part are cultivated under conditions which are not favourable to their growth. The converse, although equally well proved, is probably true also,—that a virus of low intensity increases in virulence if cultivated in a medium suited to its growth and development. Such a medium for the growth of pathogenic organisms is found in the feeble tissues and unhealthy sores of patients weakened by breathing the impure atmosphere of an over-crowded ward, and it is thus that infective processes of intense virulence may be developed. Our knowledge of the conditions under which the virus is developed in hospital gangrene and pyæmia, is still very far from perfect; but this much is certain, that they are essentially filth-diseases, and may, if the term be allowable, be manufactured in any hospital or house, however clean or well situated, by the accumulation within it of too large a number of patients suffering from wounds the discharges of which are in a state of decomposition. It is probable that the contagia of some of these diseases are destroyed by oxidation, especially if at the same time they are exposed to bright sunlight; but, be this as it may, it is evident that a want of free ventilation must lead to a concentration of such poisons as are disseminated by the air, and at the same time the patient's body will be rendered more susceptible to their influence as its vitality becomes lowered.

In the prevention of the effects of over-crowding we have to consider first the vitiation of the air by the natural processes of respiration and excretion; and, secondly, fouling of the atmosphere by the emanations from wounds and sores. The first of these causes of impurity is unavoidable, and it is only by providing sufficient air for each patient and changing it with sufficient frequency that its evil effects can be prevented. In determining the condition of the air of a room or ward the carbonic acid present is taken as the index of the degree of impurity, as it is easily estimated, while the determination of the organic matter is almost impossible. Parkes and De Chaumont give 16 per 1000 volumes of total carbonic acid in the air as the limit of impurity allowable. Of this about 12 is derived from respiration and the remainder is the normal quantity present in the atmosphere. In order to maintain the air at this standard an ordinary man requires to be supplied with 2000 cubic feet per hour. This is the minimum quantity of air that will suffice for the purpose, and it would evidently be unwise to trust to this. The rule, then, laid down is that at least 4000 cubic feet per hour must be provided. In order that this amount of air may be obtained without exposing the patient to draughts, a sufficient cubic space must be allowed for each patient, so that if the air be changed from three to four times per hour the requisite amount may be supplied. Under exceptional circumstances 1000 cubic feet per head might thus, with good ventilation, be made sufficient; but

no surgeon would be content with this if he could obtain more ; as in civil practice he always can. The rule, therefore, laid down in the construction of hospitals is that each patient shall be allotted from 1500 to 2000 cubic feet of space, the larger space being required for infectious, or surgical cases. In order to maintain a proper degree of separation of the patients each must be allotted from 100 to 120 square feet of floor. The effective height of a ward for the purposes of ventilation does not exceed 12 feet. Not only, however, is space required, but change of air, by proper ventilation, is equally needful. Military experience has shown conclusively that churches form the worst possible hospitals, for in these buildings, although the cubic space per head is frequently enormous owing to the great height of the building, the floor area is comparatively small, and little provision is usually made for efficient change of air.

The second cause of vitiation of the air of a surgical ward—the emanations from wounds and sores—is more or less completely under the control of the surgeon. Wounds do not necessarily add to the impurity of the air of a ward ; it was the decomposition of the discharges and the effluvia so developed that gave rise to the evil consequences formerly so familiar to most surgeons. Experience tends to show that if decomposition of the discharges be absolutely prevented, a case with a wound vitiates the air of a ward no more than one without ; and in the present day, when the powers and properties of antiseptics are so well understood, there is never any excuse for a wound becoming a source of impurity to the surrounding air. Should decomposition be unavoidable, as it still is in many cases, it is easy to absorb the discharges in some antiseptic dressing, which will completely disinfect them as soon as they leave the patient's body. No surgeon doubts that an accumulation of putrid wounds in a ward gives rise to unhealthy processes, such as pyæmia, septicæmia, hospital gangrene, and the like. If such diseases do arise, most are agreed that the ward must be thoroughly disinfected before it can safely be used again. Surely it is more rational to commence the disinfection at the source of mischief—that is to say, the wound.

A sufficient cubic space, free ventilation, and clean wounds, are therefore the essentials of a healthy hospital. Attention to these three conditions, especially the last, has in many Continental hospitals reduced the death-rate to less than a quarter of what it was in former times. Care must be taken in attending to ventilation, that the free current of air is maintained both by night and day. It is from want of this precaution during night especially that much mischief often results. The importance of maintaining efficient ventilation during night, and the little danger to be apprehended from the admission of cold night air, were so forcibly pointed out by Miss Nightingale in *Nursing*, and are now so universally admitted, that I need not add the testimony of my experience to the truth of her statements. In cold weather, also, there is so great a disposition for patients to shut up wards and rooms, that the air becomes so contaminated ; and hence it is that erysipelas is so common during winter and early spring. The cold is the cause of these ; and no doubt the windows and doors to be shut, so as to prevent draughts and panics that wind. It is impossible to supply of pure air in less

hospitals, but equally in private dwellings. The fact has often been observed in military practice, and the Franco-German War brought it into strong relief—that those wounded fare best who are treated in open huts or tents, whilst those who are placed in the apparently more favourable conditions afforded by regular houses become decimated by those scourges of military surgical practice, pyæmia and hospital gangrene. It is the difference in the hygienic arrangements in hospitals that, more than any other condition, influences the varying rate of mortality in different institutions; and it is obvious that, *ceteris paribus*, those patients will have the best prospect of recovery who are most scrupulously attended to in this respect; that no cases of operation should be placed in ill-ventilated wards, or in those that contain more than a certain percentage of patients suffering from wounds or sores, the discharges from which are unavoidably foul; and that the performance of operations in close and ill-ventilated rooms, or in houses situated in over-crowded neighbourhoods, should, as far as possible, be avoided. The faulty hygienic conditions that are still too frequently met with in hospitals, are alike a cruelty to the patient and an injustice to the Surgeon. The cruelty to the patient consists not only in exposing him to an increased chance of death—or, as it is commonly called, “to a higher rate of mortality” from septic diseases that are preventable, and that are the direct outcome of the defective hygienic arrangements of the institution—but in subjecting him to a prolonged and imperfect convalescence; either or both of which conditions may be taken as the measure of the neglect of sanitary arrangements in a hospital.

But want of attention to sanitary hospital arrangement is equally an injustice to the Surgeon. His reputation suffers by an increased rate of mortality amongst his patients from causes which, though preventable, are altogether beyond his control; an undue burden of anxiety, responsibility, and care is thrown upon him by the necessity under which he lies of waging a constant warfare against septic hospital influences.

Attention to hospital hygiene is by no means of so modern a date as many appear to suppose. The Surgeons of the last century paid great attention to it, and their success was proportionately great. Thus Alanson's success in amputations has never been surpassed, and rarely, if ever, equalled even with the aid of antiseptics and of every modern appliance. Writing in 1782 (“Alanson on Amputation and the After-treatment,” London, 1782), he says (Preface, p. 15), that he amputated in thirty-five cases, such as promiscuously occurred in the Liverpool Infirmary, *without the loss of a single patient*. The symptomatic fever was slight, and there was not an instance of secondary hæmorrhage in the whole series. Alanson was a sanitary reformer in his day; and had his instructions been followed, thousands of lives would have been saved which have since his time been wantonly sacrificed by the neglect of hygienic measures. His advice is so practical that it deserves the attentive study of the modern Surgeon. He says: “The air in which the case is to be conducted is a point worthy of your greatest attention: if possible, the room should be spacious, and in an open, wholesome situation. It is well known that in hospitals which are situated in populous towns and are much crowded, the salutary influence of the air is so altered, that compound fractures and other important surgical cases prove peculiarly fatal, and that such fractures may almost certainly be cured in the country.” . . .

“The operation of amputation done in the country, as above described, will

be followed almost certainly with a speedy cure ; there the consequent symptoms are trifling, nearly the whole internal surface of the wound unites by the first intention, the suppuration consequently is small." . . .

" Many hospitals are so tainted by unwholesome effluvia that they are rather a pest than a relief to the objects they contain." (Op. cit., pp. 89—92.)

Then follow sixteen distinct paragraphs or heads of the most useful sanitary advice, which " are humbly recommended to those who have the care of hospitals in want of such attention."

This code of regulations deserves careful study. In it Alanson advises :

That no ward should be inhabited for more than four months at a time ; that it be cleansed, whitewashed, and purified. That the " bed-stocks " be of iron ; the bedding frequently changed, and made of inexpensive materials so that it may easily be renewed ; and that when the weather admits, it be exposed to the open air for several hours a day. That dirty patients be stripped of their clothing before admission ; that they have a warm bath and then be clothed in dresses provided by the hospital. That the infected clothes be baked in a properly constructed oven. That newly admitted patients be put into clean, well-ventilated wards. That all incurable and infectious cases, and especially chronically ulcerated legs, be refused admission. That offensive gangrenous and putrid sores be placed in distinct rooms, and not suffered to infect a whole ward. That there should be particular rooms provided for patients who have undergone operations ; that they should be airy, never long inhabited, and afterwards cleansed and ventilated. That a hospital should never be crowded *on any account*, and always so large that a part may be uninhabited. That the windows be opened for a certain number of hours daily. And lastly, that every hospital should have a " house in the country," in other words, a " convalescent home," attached to it. Modern science has enabled us to determine the true nature of those conditions that lead to hospital infection, but sanitary practice has not as yet gone in advance of the admirable precepts laid down by Alanson more than a century ago.

The mortality arising from inattention to these various hygienic conditions, whether want of cleanliness in the wound or want of pure air in the ward, is not a necessity of the operation, but rises and falls according as the treatment of the wounds, or the circumstances in which the patient is placed, depart more or less widely from those conditions that are necessary to the maintenance of health. The frequency of the occurrence of erysipelas in an institution may be taken as an indication of neglect in its sanitary arrangements. Pyæmia and septicæmia as a rule indicate, in addition to general neglect, a want of cleanliness in the wounds, and reflect to a certain extent upon the Surgeon as well as the institution. These diseases are preventable, and ought to be prevented. Surely the first and most essential requisite of a hospital is that it be not a source of disease to its inmates—that those who are compelled to seek its aid shall not suffer from its effects.

The exposure of a patient after an operation to the *contagious emanations* of septic diseases from other sick or wounded patients, is attended with the most fatal consequences. Whenever it is practicable, every case of septic disease, such as pyæmia, erysipelas, inflamed lymphatics or veins, or hospital gangrene, should be rigorously excluded from the ward or room in which other patients with operation-wounds happen to be lying ; and, if possible, the same nurses, dressers, or surgeons should not be allowed to go from the infected to

the healthy, nor should the same appliances, dressings, or sponges be used for both. When this is not possible, the danger of infection may be greatly diminished by the free use of antiseptics to the wounds both of the infected and the healthy. Great care also should be taken in the purification of the bedding that has been used by patients suffering from septic disease; the blankets especially are apt to harbour infection long, and must be thoroughly disinfected by heat or by efficient chemical antiseptics.

3. The **Special Conditions directly excited by the Operation itself** predisposed to by the circumstances that we have just been considering, and commonly leading to a fatal result, of which they are the immediate occasion, are the following: Shock, Exhaustion, Hæmorrhage, Gangrene, Tetanus, Pyæmia, Septicæmia, Erysipelas, and other Diffuse Inflammations. These causes of death are so various, and comprise so many distinct diseases, that I shall do little more here than mention them; referring the reader to the different chapters in the body of the work, in which each is specially treated.

The *Shock of an Operation* may prove fatal in various ways: from the severity of the mutilation, as in a case of double amputation; from the nervous centres being implicated, as in the removal from the face of large tumours that have connections with the base of the skull; from fear, or from the state of nervous depression into which the patient has previously fallen, causing him to feel the influence of an operation disproportionately to its severity. These various effects of shock have, however, been much lessened since anæsthetics have been generally administered in operative surgery. Anæsthesia, however, does not remove the physical impression produced on the system by a severe mutilation; hence the influence of a serious and prolonged operation is still manifested in the production of shock, of collapse, and of slow recovery, even though the patient have suffered no actual pain. Certain operations appear to exercise a peculiarly depressing effect on the nervous system, even though no pain be experienced. Thus, in castration, at the moment of the division of the spermatic cord, the pulse will sink markedly, even though the patient have been fully anæsthetised.

Exhaustion, without any tangible local or constitutional disease, is an occasional cause of death after severe operations; more particularly in delicate females, in feeble or debilitated subjects, in those who have lost much blood, or who have become weakened by protracted suppuration. A large number of the deaths formerly recorded as due to exhaustion were doubtless the effect of slow poisoning from the absorption of putrid matter from unclean and imperfectly drained wounds.

Hæmorrhage, if very copious, may be immediately fatal; or may increase the shock so that the patient cannot rally; or, by weakening him and lowering his vitality, it may render him more liable to be affected by unhealthy inflammations and septic processes, which frequently terminate in death. The danger from these secondary and indirect effects of excessive hæmorrhage is very great. Blood once lost is not easily replaced in advanced life, and at any period its excessive loss may permanently impair the constitution. It has been shown by experiment that animals previously weakened by loss of blood are more readily infected by pathogenic organisms than those in a normal condition, and this explains the fact that patients who have lost much blood make slow recoveries, often interrupted by intercurrent diseases which

may prove fatal. For these reasons hæmorrhage should, as much as possible, be prevented during the performance of an operation.

When hæmorrhage occurs within twenty-four hours of an operation, it usually proceeds from imperfect ligature of the vessels or from arteries bleeding after the commencement of reaction, which had not furnished blood whilst the patient was under the influence of the shock of operation. On recovery from anesthesia also, it not unfrequently happens that arteries begin to spout, which yielded little or no blood whilst the patient was insensible. In these circumstances, hæmorrhage is of far less moment, and is less frequently fatal, than when it occurs at a later period, in consequence of some morbid condition of the wound, and frequently in association with local diffuse inflammation or general infective processes.

Gangrene from purely local conditions, as in a limb from excessive traumatic violence, or in a strangulated hernia in consequence of prolonged strangulation of the gut before operation, is an occasional cause of death.

Tetanus but rarely occasions death after operations in this country. When it does occur, it is more frequently after the lesser than after the greater operations that it develops itself.

Internal Inflammations of an acute character may carry off the patient after an operation in two ways. Inflammation of this kind may have existed antecedently to the operation, being the disease for which it is performed : and, being unchecked by the operation, may continue its course and destroy life. Thus, when a child dies after tracheotomy for diphtheria, death is not in general occasioned by the operation, but by the extension into the lungs of the disease for which it has been performed. Or the inflammation may be the consequence of the operation : as when peritonitis occurs after the operation for strangulated hernia, or meningitis after the skull has been trephined. But it is not by the action of any of these direct results that an operation usually proves fatal. In the great majority of instances, death is occasioned in a more indirect manner by the development of infective inflammations, to which a neglect of hygienic laws acts as a powerful predisposing cause.

Local and General Infective Diseases of septic origin, such as wound-diphtheria, hospital gangrene, erysipelas, pyæmia and septicæmia, were formerly frequent causes of death, more particularly in large towns. They were the dread of surgeons and the scourges of hospitals, and to them were probably due three-fourths of all deaths after operations. This proportion has, however, been greatly reduced by improved methods of treating wounds, and greater attention to the sanitary arrangements of our hospitals. In the production of these diseases, an impure blood, loaded with effete materials retained through habitual disregard of the ordinary rules of health or through defective elimination by the kidneys and skin, acts as a potent predisposing cause. In these circumstances, it is not the extent of the wound that determines the dangerous results. A mere breach of surface, however trivial, is sufficient to form a starting point for these morbid processes. The amputation of a toe may be as fatal as that of the thigh, or the removal of a small atheromatous cyst of the scalp as the ablation of the breast ; the only additional danger essentially connected with the greater operation being the increased risk from shock and hæmorrhage.

PREPARATION FOR OPERATION.

The Surgeon, being convinced of the necessity of an operation, should fully lay before his patient the state of the case, in order to obtain his consent and that of his family. In the event of the patient refusing to submit, the Surgeon must be guided partly by the nature of the proposed operation: and partly by the state of the patient, and his capability of forming a correct judgment of his case. If the operation be one of expediency, merely for the relief of an infirmity or the removal of an ailment which does not directly jeopardise life, no Surgeon would think of undertaking it without the full consent of his patient. If, on the other hand, it be an operation that is necessary for the preservation of life, in which delay may be fatal, as in one of the four cases of surgical urgency, viz., dangerous hæmorrhage, asphyxia, over-distended bladder, or strangulated hernia, and if the patient, unaware of, or incapable of being made to understand, the necessity for immediate action, be unwilling to assent to the proposal, the Surgeon will truly be placed in a dilemma of anxious responsibility; between allowing the patient to fall a sacrifice to his obstinacy, ignorance, or timidity, and attempting, perhaps unsuccessfully, to rescue him from death without his consent. I believe the proper course for the Surgeon to pursue under such circumstances, is to judge for the patient in a matter on which he is clearly unable to form an opinion, and to compel him, so far as is legal and practicable, to submit to the necessary steps for the preservation of his life, or to put him under an anæsthetic, and, when he is unconscious, to perform any operation that may be required. In the event of the patient being insensible, as after an injury of the head, the Surgeon must necessarily take upon himself to act as the case requires. Children cannot be considered capable of giving an opinion as to the propriety of an operation; the consent of the parents alone is necessary; and, in their absence, if the case is an urgent one, the Surgeon must stand *in loco parentis*, and take all responsibility upon himself.

In order to persuade a patient to submit to a necessary operation it is often advisable to speak to him more encouragingly than the circumstances may justify, but if this be done the wife or husband or next friend must be made acquainted with the exact state of the case. In the after-treatment the same rule must be followed. It would often rob a patient of his last chance of recovery to tell him that his life was in imminent danger, but the fact must never be concealed from his friends, and the responsibility of communicating it to him, if they think fit to do so, may be left with them.

These points having been determined, the patient should, if possible, be *prepared for the operation*. In a great number of cases requiring operation, as in strangulated hernia, bad compound fracture, &c., no time is allowed for preparation, but the Surgeon must at once submit the patient to the knife, whatever the state of his health may be. But in the more chronic cases, time is given for improving the constitution. This preparation must not consist of any routine system of purging and starving, which is ill calculated to make the constitution fit to meet the call that will be made upon its powers; nor, on the other hand, in blindly adopting a tonic or stimulating regimen; but in adapting our means to the condition of the patient and the nature of the operation to be performed. The tendency to erysipelas, pyæmia, and diffuse inflammations generally, is materially lessened by supporting the

ferments in decomposition; thirdly, from the presence of dried particles of the discharges from wounds or sores; and, lastly, by the contagia of specific infective processes, whether general or local.

The gaseous products of decomposition, consisting of sulphuretted hydrogen, sulphide of ammonium, free ammonia, carburetted hydrogen, carbonic acid, and many others undoubtedly tend to aggravate the symptoms produced by the accumulation of the products of respiration; but it is impossible to separate the effects produced by the former from those of the latter, with which they must almost necessarily be complicated in a hospital ward. Parkes states that the putrefying animal matter which frequently accumulates about camps during war forms one of the principal causes of diarrhoea and dysentery; but it is only in military practice in which large numbers of wounded must occasionally be packed closely together and their wounds neglected for want of sufficient surgical assistance, that putrid discharges could accumulate to such an extent as to develop these diseases.

Secondly, the air of a ward containing many foul wounds has been shown to contain a great excess of organic matter, but it is impossible to separate the effects produced by it from those of foul air generally.

Thirdly, microscopic examination has demonstrated the presence of dried pus cells in the air of surgical wards in addition to the epithelium always met with in inhabited rooms. It has been supposed by some that these might possibly act as the material of contagion; that they may be the bearers of contagion cannot reasonably be doubted.

Lastly, the air of surgical wards is apt to be contaminated by the contagia of specific infective processes, such as hospital gangrene, erysipelas, pyæmia, &c. The exact nature of the contagium in all these diseases is not yet definitely ascertained. This much is certain, that the poison in all is particulate; it is never gaseous. Its activity can be destroyed by those chemical substances that we class as antiseptics. In the majority of cases the specific infective process commences in a wound, the discharges of which are in a putrid state; and those methods of treatment which are best calculated to prevent putrefaction also serve best to prevent the occurrence of infective processes, either local or general. It may now be said to be practically proved that all these unhealthy spreading inflammations are accompanied by the presence of microscopic organisms in the discharges, and often in the lymph spaces near the wound: and the view is now universally accepted that these micro-organisms are directly or indirectly the cause of the unhealthy processes, and that infection is brought about by the actual transference of some of these living particles from one patient to another. In the human subject erysipelas has been definitively proved to be caused by the invasion of the lymph-spaces of the skin by a specific fungus. Koch has shown that diseases closely resembling gangrenous erysipelas, septic infection, and pyæmia, as they occur in the human subject, can be artificially produced in animals; that each disease is accompanied by the presence of a distinct form of micro-organism, and that it can be transmitted from one animal to another by means of infinitesimal quantities of the blood or exudation fluids containing the characteristic organism. That the organisms or their spores retain their vitality after being dried has been clearly proved with regard to the somewhat analogous disease of anthrax in cattle. This disease is due to a rod-shaped organism, the *bacillus anthracis*, of such size that its life-

history can be accurately studied. It has been found that under certain conditions minute spores are developed in the bacillus, and that when this has taken place blood containing the virus may be dried and kept in that state for years without losing its virulence. In this state it is easily conceivable that it could be disseminated by the air. It is well known that the virus of vaccinia, small-pox, and scarlet fever equally resist the effects of drying.

Another fact of equal importance, which was first discovered by Pasteur and Toussaint, is that the virus of splenic fever and that of a peculiar form of septicæmia, common in fowls, known as chicken cholera, lose considerably in virulence if the organisms which form their essential part are cultivated under conditions which are not favourable to their growth. The converse, although equally well proved, is probably true also,—that a virus of low intensity increases in virulence if cultivated in a medium suited to its growth and development. Such a medium for the growth of pathogenic organisms is found in the feeble tissues and unhealthy sores of patients weakened by breathing the impure atmosphere of an over-crowded ward, and it is thus that infective processes of intense virulence may be developed. Our knowledge of the conditions under which the virus is developed in hospital gangrene and pyæmia, is still very far from perfect; but this much is certain, that they are essentially filth-diseases, and may, if the term be allowable, be manufactured in any hospital or house, however clean or well situated, by the accumulation within it of too large a number of patients suffering from wounds the discharges of which are in a state of decomposition. It is probable that the contagia of some of these diseases are destroyed by oxidation, especially if at the same time they are exposed to bright sunlight; but, be this as it may, it is evident that a want of free ventilation must lead to a concentration of such poisons as are disseminated by the air, and at the same time the patient's body will be rendered more susceptible to their influence as its vitality becomes lowered.

In the prevention of the effects of over-crowding we have to consider first the vitiation of the air by the natural processes of respiration and excretion; and, secondly, fouling of the atmosphere by the emanations from wounds and sores. The first of these causes of impurity is unavoidable, and it is only by providing sufficient air for each patient and changing it with sufficient frequency that its evil effects can be prevented. In determining the condition of the air of a room or ward the carbonic acid present is taken as the index of the degree of impurity, as it is easily estimated, while the determination of the organic matter is almost impossible. Parkes and De Chaumont give 4 per 1000 volumes of total carbonic acid in the air as the limit of impurity allowable. Of this about .2 is derived from respiration and the remainder is the normal quantity present in the atmosphere. In order to maintain the air at this standard an ordinary man requires to be supplied with 3000 cubic feet per hour. This is the minimum quantity of air that will suffice for the purpose, and it would evidently be unwise to trust to this. The rule, therefore, laid down is that at least 4000 cubic feet per hour must be provided. In order that this amount of air may be obtained without exposing the patient to draughts, a sufficient cubic space must be allowed for each patient, so that if the air be changed from three to four times per hour the requisite amount may be supplied. Under exceptional circumstances 1000 cubic feet per head might thus, with good ventilation, be made sufficient; but

gave rise to much discussion: viz., Do they influence the rate of mortality after operations? Simpson published statistics to show that the death rate was lessened by their introduction, while J. Arnott adduced figures to prove that it was materially increased: in amputation by 12 and in lithotomy by as much as 28 per cent. I am inclined to think that the rate of mortality was at first increased, and that this was due to two causes. First, that the Surgeon in his anxiety to give his patient a chance of life, not unfrequently operated by the aid of anæsthetics for diseases or injuries which would formerly have been left without an attempt at relief, and, secondly, that the introduction of anæsthetics led at once to an enormous increase in the number of operations performed. Hence hospital wards became more crowded than formerly with severe operation cases, and in the absence of any efficient antiseptic treatment, the causes of septic diseases became much more rife, erysipelas, septicæmia, pyæmia, and hospital gangrene more frequent, and the mortality proportionately increased. At the present time, however, owing to the improved treatment of wounds and better sanitary arrangements the mortality after operations is certainly lower than it ever was before the days of anæsthetics. Although, therefore, the statistics of modern surgery show no evidence of an increase of mortality due to the employment of anæsthetics, I cannot but think that chloroform and ether do exercise a noxious influence and lessen the prospect of recovery in certain cases. In some, especially if the kidneys are diseased, the prolonged vomiting that often follows their administration may depress the patient to such an extent that he may fail to rally after the operation. In other cases the irritating vapour either of ether or chloroform may aggravate existing bronchitis to a fatal degree. Some, therefore, purchase the immunity from suffering by a lessened chance of recovery, but there is no reason to believe that this is the case with a patient who at the time of the operation is in good health save for the local disease for the relief of which the operation is undertaken.

ADMINISTRATION OF ANÆSTHETICS.—Anæsthetics should never be given by a person unaccustomed to their use, and on whose capability the Surgeon has not full reliance: as nothing is more embarrassing during an operation than to have any doubt about the anæsthetic being properly administered. It must not, however, be imagined that they can be safely given only by a specialist. Every student before leaving the hospital may easily make himself sufficiently acquainted with the details of their administration to enable him to give them with perfect safety, provided he pays undivided attention to what he is doing and does not allow his mind to be diverted by watching the operation or by attempting to act both as anæsthetist and assistant.

No anæsthetic should ever be administered, except in cases of great emergency, to a patient who has eaten anything within three or four hours, lest it induce vomiting of the partially digested meal. On the other hand, the patient should not be exhausted by want of food, as may happen if the operation be performed early in the morning. Thus, if 9.30 be the hour fixed, he may have a cup of strong beef-tea at 6.30. Before any anæsthetic is administered, the patient should be asked if he wears false teeth, and if so, they should be removed. Any article of clothing about the neck, chest, or waist, that might cause interference with respiration or circulation must be loosened, and the patient should then be placed, if possible, in the recumbent position.

It is not necessary in all operations to administer the anæsthetic to the same extent. In the greater operations, such as amputation, lithotomy, or the ligation of an artery, enough should be given to completely paralyse muscular movement, as well as to suspend consciousness. In operations for hernia, also, and all other proceedings implicating the abdominal walls, if complete muscular relaxation be not induced, great inconvenience and no little danger may result. So, also, in very painful operations about the anus and genital organs, a full dose should be given. But for minor operations of short duration, it will be sufficient to give enough merely to suspend sensibility without inducing complete muscular relaxation.

Administration of Ether.—The best washed sulphuric ether should be used for anæsthetic purposes. Its specific gravity should be about $\cdot 720$, and it should be free from alcohol, water, and fusel oil; the first two impurities may be recognised by the higher specific gravity of the mixture, and the last by a greasy stain left on paper, on which the ether is allowed to evaporate. Pure ether does not redden litmus paper. It should be kept in a well-stoppered bottle in the dark to prevent decomposition.

The administration may be effected by the application over the mouth and nostrils of a hollow sponge, or a towel folded into the form of a hollow cone, saturated with the ether; but it is better to employ some form of inhaler, as from its extreme volatility, unless some means are taken to economise it, the quantity required becomes a serious inconvenience. When given by means of a sponge, the face may be greased to prevent the pungent effects of the ether on the skin.

Amongst the numerous inhalers which have been invented of late years, Clover's smaller apparatus is perhaps the best (Fig. 1). It consists of a face-piece to cover the mouth and nose, to which a circular metal vessel to contain the ether is attached by a short metal tube. On the other side of this is a thin india-rubber bag, also connected with the ether-chamber by a short tube. The ether-vessel can be rotated on the face-piece, and according to the position in which it is placed, the course of the air passing through the apparatus varies. When it is turned so that the small indicator points to "no ether," the expired air passes into the bag without entering the ether-chamber, and is breathed again at the next inspiration. When at "full ether," the air in inspiration from the bag and expiration into the bag must all pass through the ether-chamber, which is warmed partly by the patient's breath, and partly by the administrator's hand on the outside. By a simple mechanical arrangement these variations in the direction of the air are effected without valves, and the instrument is for this reason less likely to get out of order. It is used in the following manner: Two ounces of ether are first poured into the ether-chamber, and the face-piece is fitted to the patient's face

Fig. 1. Clover's Ether Inhaler.

with the ether-chamber, but without the bag, and with the indicator pointing to "no ether." The patient is allowed to breathe through it a few times to get accustomed to it. Then the bag is applied, and he commences to breathe the same air over and over again. This soon produces a slight stupefying effect, and after a few respirations the ether-vessel is rotated so as gradually to allow more and more ether-vapour to be mixed with the air. After a few more respirations the full amount of ether should be turned on. In this apparatus there is purposely no provision for the admission of fresh air, and if it were held firmly to the face for a sufficient time death from asphyxia must ensue. The administrator judges by the appearance of the face when air is needed, and removes the whole apparatus for one or more respirations as he may think necessary. Clover recommended that it should be removed at every sixth inspiration. The administration of ether by this apparatus gives rise to less choking than when the vapour is given from a hollow sponge.

The first effect of the administration of ether is to cause some irritation of the air passages indicated by coughing and a sense of suffocation, often very distressing to the patient, especially if the vapour be at first administered in too concentrated a form. This is very much diminished or completely avoided by using Clover's apparatus in the manner above described. After a few inspirations the sense of irritation subsides, and the vapour may then be given in full strength. The face soon becomes flushed, the breathing more deep and rapid, and the pulse is increased in frequency and fulness. At this time the patient feels a sense of warmth and tingling throughout the body. This stage is quickly followed by one of excitement, in which the patient may struggle, often violently, with the administrator and his assistants. His movements are more or less purposive, like those of a drunken man. This stage of excitement is most marked when the vapour is considerably diluted with air, as when it is given by means of a cone. The use of a good inhaler tends to shorten it, or to abolish it altogether. The patient frequently remembers what has happened during the stage of excitement, and the surgeon and his assistants should avoid any unguarded expression which might leave on the patient's mind an idea that he was roughly used. The face now becomes dusky, the skin is covered with perspiration, the respirations are hurried and deep, the pulse strong and full, and the pupil contracted. At this time a bright red rash not uncommonly appears on the chest and neck. The stage of excitement is usually followed by one of general muscular rigidity, the limbs are forcibly extended, the respiration may be temporarily suspended, and the duskiness of the face increased. The inhaler should now be removed for a few seconds till another breath has been taken. If the inspiration is delayed, the chest may be squeezed and the chin forcibly pulled up, which will usually have the desired effect. The stage of rigidity is quickly followed by complete muscular relaxation, the respiration becomes slower and shallower, the pulse falls slightly in frequency and force, the face becomes less dusky, the pupil dilates and the conjunctival reflex is abolished. The patient is now ready for the operation. A smaller quantity of ether is required to maintain the desired condition, and if Clover's apparatus is being used, it may be turned to "one-third" or "one-half ether." From the earliest stage of administration, the flow of saliva and mucus from the mouth and air passages is increased, often to such an extent as to cause considerable embarrassment in breathing, the respiration, both abdominal and thoracic, being violent and laboured. Under

these circumstances, the pharynx must be cleaned out occasionally with a sponge on a holder, and the head may be turned to one side to allow the secretion to flow from the mouth. However inconvenient these violent respiratory movements may be to the surgeon, he must not be tempted to change the anæsthetic to chloroform, as in the semi-asphyxiated state of the patient, there is great danger in so doing.

Experiments on animals have shown that the blood-pressure is at first increased during the administration of ether, and only falls when the animal is very deeply under its influence. The temperature is slightly reduced by prolonged administration.

The time required for the induction of anæsthesia varies, averaging about five minutes if the ether is administered without an inhaler, but much less if Clover's apparatus be used. Habitual drunkards often require a large amount of ether to produce anæsthesia.

Secondary Effects of Ether.—Headache and prolonged drowsiness may follow the administration of ether, especially in the aged. In young and nervous women, hysterical excitement may appear and continue for some hours, or even days, but this need not excite uneasiness.

The lungs probably always become slightly congested during the administration of ether, but as recovery takes place, the pulmonary vessels unload themselves, and no inconvenience usually results. This is facilitated by admitting an abundant supply of fresh air to the room, and desiring the patient to breathe several times fully and deeply after consciousness returns. In some cases the lungs do not unload themselves of the accumulated blood and of the excess of bronchial secretion that accompanies the congestion, and a process of slow asphyxia may set in, and prove fatal in a period varying from twenty-four hours to four or six days. This occurs in old patients suffering from chronic bronchitis and emphysema, and is not an uncommon cause of death after operations for strangulated hernia, as the strangulation is frequently caused by violent straining in coughing. It is also especially apt to happen in those cases in which it becomes necessary to bandage the chest, or in which deep respiration is attended with pain, as after amputation of the breast. Great care must, therefore, be taken not to constrict the chest-walls too tightly after such operations.

Continual nausea and vomiting are sometimes very distressing after-effects of ether, and may be productive of serious and even fatal results. Vomiting is less likely to occur if the patient can be left undisturbed and allowed to sleep off the effects of the anæsthetic. In many instances it is caused by the patient taking the ether too soon after a meal, and is then purely gastric, and usually occurs early in the administration. In other cases, it appears to depend upon cerebral disturbance of some kind, and in others, again, it is connected with kidney disease. But in any case, and from whatever cause arising, it is a serious symptom, and, if it continue, may turn the scale against the patient by the exhaustion to which it gives rise. It is best treated by ice or weak iced brandy and soda-water. Strong iced black coffee with bromide of potassium is occasionally useful, and in extreme cases a mustard plaster or even a blister to the epigastrium may be tried. Dudley Buxton recommends sipping hot water from a feeder or cup. About a teaspoonful should be taken at a time, and the temperature must be as high as the patient can bear. Tepid water increases the vomiting. For prolonged nausea, he advises

the administration of one minim of tincture of *nux vomica* in a teaspoonful of hot water every ten minutes for one hour.

In *certain diseased conditions*, such as, early phthisis, chronic bronchitis, and various forms of heart disease, the administration of ether requires much care. In persons who are epileptic, and in red-faced apoplectic-looking men, it must be cautiously administered, as in the early stages it is apt to cause much cerebral excitement. Ether is usually considered to be especially dangerous in advanced kidney disease. These conditions will be more fully discussed when considering the choice of an anæsthetic (p. 35).

Death from the Administration of Ether may arise from various causes. Cantley Dawson, in the *British Medical Journal*, March 2, 1878, published a collection of eighteen cases in which death took place either during or soon after the administration of ether. Of these he excluded nine, on the grounds that ether was not the only anæsthetic used, or that it was possible the death might have been due to other causes. Of the remaining nine cases, in seven the heart continued to beat for some time after respiration had ceased, and in two this point was doubtful. All the patients died from asphyxia, as indicated by the dusky face, the shallow respiration, and the long interval, varying from four minutes to fifteen or more, between the first manifestation of serious symptoms and death. At the post-mortem examination the lungs were found gorged with blood in five of the seven cases examined: in one more "the pulmonary artery was said to be engorged"; in one only were the lungs pale, and in this case the symptoms did not come on till one hour and a half after the patient had left the operating theatre. These cases confirm the generally received opinion, founded on experiments on animals, that ether kills by acting primarily on the respiratory centre, and that the heart is never affected first. Ether is said, therefore, to possess the advantage that, when it does give rise to dangerous effects, the serious symptoms develop gradually, and give plenty of time for the adoption of the necessary measures to restore the patient. Amongst the fatal cases recorded, there are, however, undoubtedly some in which there seems good reason to believe that the respiration and the heart's action ceased simultaneously: but even in these, duski-ness of the face is most commonly mentioned as the first symptom, and very probably there was some degree of asphyxia before the heart ceased acting. It is quite easy to understand how a weak or dilated heart may fail under the influence of ether, in consequence of obstruction to the pulmonary circulation from the direct irritation of the lungs by the ether vapour, and from the semi-asphyxia caused by excessive accumulation of mucus in the bronchial tubes.

Many patients who were previously suffering from bronchitis and emphysema have also undoubtedly been killed by slow asphyxia consequent upon the aggravation of the disease by the irritation of the ether vapour. In a few recorded cases, death has taken place within a few hours from acute oedema of the lung.

Owing to the extremely violent respiration often met with during the inhalation of ether, blood or vomited matter is readily drawn into the air passages. In a fatal case which occurred at University College Hospital after an operation for strangulated hernia, the patient recovered consciousness and survived two hours. At the post-mortem examination, fecal matter was found in the bronchi, even in their smaller divisions.

Administration of Ether by the Rectum, which was suggested and practised by Pirogoff so long ago as 1847, has lately been advocated by Molière, Wauscher, and others, as a means of giving that anæsthetic when it is impossible to administer it by inhalation, as in operations on the jaw or tongue. The bowel should be cleaned out by a purge and an enema before the operation. The ether is placed in a bottle, connected by means of an india-rubber tube with a cannula, which is inserted into the rectum. The bottle is then gently heated in warm water. Care must be taken that no ether enters the bowel in the liquid form, as it would cause intolerable irritation. The general effects are the same as in administration by inhalation, and the dangers are also identical, with one exception. This method of administration is said not to cause the profuse secretion of mucus which is often so embarrassing during inhalation of ether. On the other hand, during administration it may give rise to considerable distension of the abdomen, and it is not uncommonly followed by diarrhoea. In a case of fibrous polypus of the nose in which ether was administered in this way for Marcus Beck by Dudley Buxton, the boy was kept most comfortably under the anæsthetic for one hour and a half. During the following night he passed two small loose motions containing much blood and mucus and innumerable columnar epithelium cells. No further unpleasant symptoms followed. The diarrhoea has, however, been known to be fatal in at least one case. Recovery is sometimes slow, and may be hastened by passing a long tube up the bowel as soon as the operation is finished. It is a question still to be determined whether this method is of any practical value. It might be serviceable in some cases of chest and lung surgery, in which there is reason to avoid the risk of a cardiac depressant such as chloroform, and in which great danger may be anticipated from the excessive secretion of mucus accompanying the inhalation of ether.

Administration of Chloroform.—Chloroform should be kept in a well-stoppered bottle protected from light, otherwise it may undergo decomposition with the formation of free chlorine and hydrochloric acid, both of which are apt to irritate the lungs. Pure chloroform is neutral in reaction: its specific gravity is 1.497. Distilled water shaken up with it, and allowed to separate by standing should not give a precipitate with nitrate of silver.

Chloroform may be administered either on lint or on a handkerchief or through an inhaler of some kind. The following is the way in which it may most safely be given without any special apparatus. The face should first be greased with cold cream or oil to prevent any accidental blistering of the skin. About a drachm of chloroform is then poured upon a piece of lint about four inches square, and four layers thick; this is held at a distance of about three inches from the nose of the patient, so as to permit a very free admixture of air with the first few inhalations of the vapour. After the lapse of about half a minute, the lint is brought nearer to the patient's nose, to within a distance of perhaps an inch, never being allowed to touch. At the same time a porous towel, not doubled, is lightly laid over the face of the patient and the hand of the operator, so as to limit the escape of the chloroform-vapour, but not to prevent the admission of air. During the whole time, it is the duty of the administrator to keep his hand on the temporal pulse, to watch the breathing, and occasionally to examine the pupils of the patient.

The method just described has been shown by experience to be one of the

most practically useful modes of administration, and to be quite as safe as any other. A committee of the Medical and Chirurgical Society of London, which reported on the administration of chloroform in 1864, determined that $4\frac{1}{2}$ per cent. is the maximum amount of the vapour which can safely be mixed with the air the patient inhales. Sir Joseph Lister has shown by experiment that the proportion given off from a folded piece of lint, used as above described, is far below this, and there is therefore no necessity for the use of the complicated inhalers which have sometimes been recommended. Whatever leads the administrator to rely upon anything but careful and continuous observation of the symptoms of the patient is an evil, and all inhalers have a tendency to do this. The only merit that can be claimed for any form of inhaler is that the mixture of chloroform and air given is of constant strength, whereas, when administered on lint, the vapour given off is most powerful immediately after the lint has been wetted with the anæsthetic, and gradually diminishes in strength as the administration continues. This may be obviated by the following plan, which is now recommended by Lister in the place of that which he formerly advocated. Put one corner of a stillish towel

Fig. 2. Junker's Chloroform Inhaler.

over the face in such a way that the point is over the chin ; opposite the forehead gather up the towel in three or four puckers, and, if necessary, pass a pin through them ; there is thus produced a concave mask, which covers the mouth and nose tolerably accurately. By allowing a drop or two of chloroform to fall upon it from a drop-bottle every few seconds, the central part is kept constantly wet over an area of about two inches in diameter. By this means a vapour of practically constant strength can be easily administered.

A useful form of inhaler in many cases is that known as Junker's (Fig. 2). In it air is blown by a bellows through a bottle to a vulcanite or flannel face-piece. The strength of the vapour inhaled depends upon the amount of air which is forced through the chloroform. Its use presents, however, no important advantage over the simpler methods of administration above described, except in operations upon the face, mouth and throat. In these the face-piece may be replaced by an elastic tube which can be passed through the nostril, so that the anæsthetic may be continuously given during the

operation. It has one special danger; if the bottle be filled too full or be accidentally tilted, pure chloroform may be blown into the mouth, or even into the lungs—an accident which has been known to be fatal. This accident may be avoided by not putting more than six or eight drachms of chloroform into the bottle, and by guarding the tube through which the vapour passes by a second one over it.

However administered, chloroform should not be given too suddenly nor in too concentrated a form. If lint be used, it must not be too much saturated nor be held too closely applied to the mouth and nostrils, or the patient may not be able to get sufficient air, and may speedily become partially asphyxiated, choking violently, struggling to get free, and becoming purple in the face. Care should be taken not to compress the abdomen in holding the patient; for, as the respiration becomes chiefly diaphragmatic, it may be seriously interrupted by any pressure on the abdominal wall. As chloroform has a sedative action on the heart, the patient should not be raised up suddenly if this can be avoided, while he is deeply under its influence, lest dangerous syncope should ensue. Hence, also, it is dangerous to administer it in those operations that require to be performed whilst the patient is erect. With due caution, it may be given with safety to individuals of all ages. I have operated on infants less than a week old, as well as on octogenarians, under its influence. In administering it to young children, Snow recommended its dilution with rectified spirit, but this is unnecessary.

The effects of chloroform resemble generally those of ether. Chloroform, however, usually gives rise to less excitement than ether, and being less irritating to the lungs, causes less choking and sense of suffocation, and scarcely any increased secretion from the pharynx and bronchial tubes. It slightly stimulates the action of the heart during the early stages of its administration, but this is quickly followed by depression with lowering of blood pressure. Muscular rigidity during the early stages is rarely as marked as with ether.

The effects of the administration of chloroform vary considerably in different patients. Occasionally the patient becomes unconscious as quietly as in the natural process of going to sleep. More commonly the first effect produced is a feeling of warmth at the pit of the stomach. This is followed by some choking sensation and violent beating of the heart, with noises in the head. At this period the patient begins to lose self-control. He talks excitedly, but not absolutely incoherently, and the struggling which frequently takes place assumes the form of efforts to remove the chloroform from his face, or to escape from the hands of the Surgeon and his assistants. At this time the pulse is quicker and more forcible than natural, the respiration is hurried and deep, the pupil acts readily to light, the face becomes flushed, and if the struggling is violent, it may be purple and turgid. This period of excitement is quickly followed by loss of consciousness. The struggling may still continue, but the movements are purposeless, and such words as he utters are disconnected and incoherent. At this stage, a violent tonic contraction of every muscle in the body may take place; respiration is arrested, and the face becomes dusky. It is wiser not to force the chloroform when this condition is present. If the lint be removed from the face for a few seconds the spasm ceases, and a few good deep respirations remove the lividity of the face, when the administration may be recommenced without danger. More commonly the stage of excitement is followed directly by that of complete insensibility,

a few deep, hurried respirations separating the two. The face now becomes pale, but not livid, the respiration is regular, slow, and shallow, the pulse falls in frequency and force, all the voluntary muscles become flaccid, and reflex movements can no longer be induced by pinching the skin or touching the conjunctiva. The pupil is at first contracted, but afterwards becomes widely dilated and insensible to light; and this is a sign that the administration has been pushed to the furthest limits consistent with safety, and must be suspended till the pupil again responds to light. Immediately before this stage is reached the patient may snore loudly; but in deep anaesthesia, the respiration, being slow, shallow, and chiefly diaphragmatic, is usually not sufficiently violent to produce any sound. What may be called the healthy snoring of deep anaesthesia must be distinguished from the loud inspiratory stertor indicative of closure of the glottis. The latter is a sign of danger, and necessitates the immediate removal of the chloroform until the stertor has passed off and has been followed by three or four healthy respirations. When fully anaesthetised, the patient is at the verge of death, and requires the most careful watching by the person who administers the chloroform; his fingers should be kept constantly on the temporal artery, as the most convenient point for feeling the pulse, and his eyes should not be taken away from the countenance of the patient. He must watch, on the one hand, for lividity indicative of impending asphyxia, and on the other, for pallor showing feebleness of the heart's action. The breathing must be carefully observed, and the administrator must not be content with seeing that the movements of respiration continue, but must feel with his hand that air is actually passing in and out, as in closure of the glottis the respiratory movements continue regularly for some time after air has ceased to enter. Many accidents doubtless arise from the patient being thus allowed to become partially asphyxiated, and the heart's action greatly enfeebled; and when, as usually happens, the obstruction passes off and is followed by a deep inspiration, instead of pure air, which is so greatly needed, a concentrated dose of chloroform vapour is supplied, which suddenly checks the action of the weakened heart.

The **Secondary Effects of Chloroform** differ but little from those of ether (p. 23). Vomiting occurs with about the same frequency and severity, and requires the same treatment. Chloroform seems to be less irritating to the lungs, and consequently gives rise to less secretion and congestion. In old bronchitic patients it may, however, like ether, aggravate the condition, and in this way indirectly prove fatal. Excitement on recovery is less common than with ether.

Death from Chloroform may occur by *Coma*, *Asphyxia*, or *Syncope*.

Death by *Coma* is very rare, and chiefly occurs in epileptics, or in patients suffering from advanced kidney disease. In these cases the breathing becomes stertorous, the face is livid, and the pupil widely dilated. There may be a general convulsion, especially in epileptics. The pulse continues to beat with good force. In spite of the removal of the anaesthetic the stertorous breathing and lividity of the face continue, the respiration gradually becoming slower and more irregular till it ceases altogether, the heart continuing to act to the last. These cases are quite exceptional: the vast majority of deaths from chloroform occur from *asphyxia* or from *syncope*.

Death by *Asphyxia* may be produced in at least four ways. 1. It has been shown by experiments on animals that chloroform will with certainty cause

death by paralysing the respiratory centre if administered in a sufficient dose, and for a sufficient time, and the same is doubtless true in man. According to the committee of the Royal Medical and Chirurgical Society (1864), if the proportion of chloroform vapour to air does not exceed $4\frac{1}{2}$ per cent. respiration will always be arrested before the action of the heart ceases. The recent Hyderabad Commission, after a prolonged and most ably conducted investigation, reported, however, that chloroform given in any dose and in any way invariably arrests respiration first. In fact, they doubt whether sudden death ever occurs from the direct action of the chloroform upon the heart or cardiac centres. Against this we must put the fact that previous observers had succeeded, or thought they had succeeded, in causing primary arrest of the heart's action, and that large numbers of apparently authentic cases are on record in which the pulse has ceased before the breathing, or both have ceased simultaneously in the human subject. The question is not yet satisfactorily settled, but this much may be said to be certain, that an overdose of chloroform kills as a rule by arresting respiration first, and only exceptionally by primarily acting on the heart. 2. It is perhaps possible that through careless administration, especially with an inhaler, sufficient air may not be admitted to maintain the respiratory function. 3. Sir Joseph Lister describes the production of asphyxia from spasmodic closure of the upper opening of the larynx, the folds of mucous membrane above the apices of the arytaenoid cartilages being carried forwards till they are in contact with the base of the epiglottis, which remains erect and unchanged in position. This theory was founded on observations of the larynx during the production of that peculiar laryngeal stertor which usually precedes the stoppage of the respiration. On pulling the tongue forcibly forward, the arytaenoid cartilages were seen to be drawn backward, and the opening of the larynx made free again; and this seemed to be due to reflex action and not to the mere mechanical act of drawing the tongue forwards. This is quite possible during anaesthesia, as the reflex functions of deglutition and respiration are not affected by chloroform as administered for a surgical operation. The closure of the glottis giving rise to this peculiar crowing stertor has been with more probability ascribed to paralysis of the abductors of the cords; but against this it may be argued that it frequently occurs before the patient is very deeply under the influence of the anaesthetic. However it may be caused, the obstruction to the respiration may pass unnoticed till the pulse stops, as the heaving of the chest may go on for some time after air has ceased to enter; the only signs of the state of the patient being the gradually increasing lividity of the face, and the fact that no air is entering or coming out, which can be ascertained by feeling with the hand over the mouth. Lister is of opinion that many of the deaths from chloroform, in which the heart has been said to stop first, were cases of this kind. He insists on the necessity of pulling the tongue forcibly forwards with forceps, and not merely drawing it out in front of the teeth, if the spasm is not immediately relieved by the simpler process recommended by Clover of pulling the chin strongly upwards. 4. Asphyxia may also be caused by the impaction of half-digested food in the larynx during vomiting, and false teeth have also been known to slip into the larynx during the administration of chloroform, and the same accident has happened with the gag used in dental operations.

In death from *Syncope* the patient becomes pale and faint; the pulse beats in a flickering manner and then ceases, though respiration may continue for

some seconds longer. This accident is more likely to occur in individuals who are depressed either by mental emotion or by physical debility, and it is not unfrequently connected with fatty heart. Death from syncope under chloroform may arise in four ways. 1. After very prolonged and severe operations, especially if associated with loss of blood, the heart's action may become gradually more and more feeble, and finally cease altogether. It is impossible in such cases to say how much is due to the chloroform and how much to the shock of the operation. 2. If the chloroform vapour be administered in too concentrated a form, it is probable that it may cause death by paralysing the cardiac centre. 3. In some rare cases death has occurred suddenly at the very commencement of the administration, before a sufficient quantity could have been absorbed to have any direct influence on the central nervous system. In these cases death is believed to be due to reflex inhibition of the heart through the vagus, the afferent impulse being developed by the irritating action of a very concentrated vapour of chloroform on the mucous membrane of the larynx, trachea and bronchi which is supplied by the sensory branches of the pneumogastric nerve. Death in these cases is due to shock. This is a very rare accident, and is probably dependent on some idiosyncrasy in the patient. 4. Death has been known to occur from reflex inhibition of the heart, owing to an insufficient dose of the anæsthetic having been given and the patient being still conscious of the pain. In these cases death might have been prevented by a more thorough administration of the anæsthetic.

If there is reason to fear syncope on account of the feeble state of the patient, a small quantity of brandy or ammonia may be given before commencing the inhalation. It has been suggested that death from reflex cardiac inhibition might be prevented by the subcutaneous injection of a dose of about $\frac{1}{16}$ grain or less of atropine, which is known to abolish temporarily the inhibitory function of the vagus. The accident is, however, so rare that few Surgeons would be found willing to give every patient a large dose of atropine before venturing to administer chloroform. It is best avoided by careful administration of the anæsthetic. The proportion of chloroform vapour to air should at first be very small and should be gradually increased. This is done by varying the distance of the lint or towel from the patient's face. Should there be coughing or repeated acts of swallowing with the first few inspirations, showing irritation of the mucous membrane of the larynx and trachea, the chloroform must at once be removed to some distance from the face and again gradually approximated.

During the whole administration the pulse and respiration should both be carefully watched. To direct attention to one only is a mistake, for, though in the vast majority of cases, the breathing will give the first indication of danger, yet we must not forget that chloroform is a cardiac depressant and in a prolonged operation may aid in inducing cardiac failure. It is the anæsthetist's duty to watch the state of the patient carefully and to warn the surgeon should he think it dangerous to continue an operation which can be abandoned or quickly brought to an end.

A few rare cases have been recorded in which, owing to an idiosyncrasy on the part of the patient, no amount of chloroform produced any anæsthetic effect.

Alcohol, Chloroform, and Ether. or, as it has been called, "the A. C. E. mixture," consisting of alcohol 1, chloroform 2, and ether 3 parts, is

sometimes useful in irritable or feeble patients. The ether is intended to prevent the depressing action of the chloroform upon the heart, the chloroform to diminish the irritation of the air passages by the ether, and the alcohol to dilute the anæsthetics. It must be administered on lint or on a folded towel, in order that the three vapours may be given off in the proper proportion. If the mixture were administered from an ether apparatus, in which the anæsthetic is put in a liquid form into a chamber in the instrument, the ether would be given off at first most abundantly, being by far the most volatile of the three, and the proportion of chloroform vapour would be gradually increased as the administration continued. For the same reason, if the mixture be not freshly prepared, the proportion of ether is apt to be diminished.

Chloroform and Morphia. In very long operations, anæsthesia may be maintained with a smaller amount of chloroform if a quarter of a grain of morphia be injected subcutaneously immediately before commencing the administration. In cerebral surgery this plan is recommended by Horsley, as the morphia temporarily constricts the vessels of the brain and thus diminishes hæmorrhage during the operation. It must be remembered that morphia, although it is safely administered with chloroform, increases the dangers of ether. Tripiér of Lyons recommends the addition of a small quantity of atropine to the morphia injection.

Bichloride of Methylene was recommended as an anæsthetic by Richardson, and a substance which passed by this name was extensively used in Guy's Hospital and at Moorfields Ophthalmic Hospital. In 1883, however, Regnaud and Villejean published a paper, in which it was shown that the liquid sold under this name is nothing more than a mixture of four parts of chloroform with one part of methylic alcohol. The advantages claimed for this mixture over pure chloroform and ether were, greater rapidity of action, complete and rapid recovery, and the absence of muscular rigidity during administration, and of unpleasant after-symptoms. The rapidity of action was, however, obtained by giving the vapour in as concentrated a state as possible, all unnecessary admission of air being avoided. It is evidently not a safe proceeding to administer any preparation of chloroform in this way. If it be used at all, it must be given in the same way, and with the same precautions as pure chloroform.

Nitrous Oxide Gas was the first anæsthetic used, but its employment was soon discontinued, ether, and subsequently chloroform taking its place. It was re-introduced in 1803 as an anæsthetic by the American dentists. It is an admirable anæsthetic, rapid in its action, safe in its administration, and seldom giving rise to any unpleasant after-effects. The class of cases in which nitrous oxide is applicable is restricted, owing to the short duration of the anæsthesia produced by it, and the suddenness of the return to consciousness, making the after-smart of the operation almost as severely felt as the cut itself could have been. Nitrous oxide is chiefly of use in operations which involve no cutting, as in the forcible bending of stiffened joints, the avulsion of the nails, extraction of teeth, &c. ; or in those cutting operations which are completed by a single stroke of the knife, as the opening of an abscess.

In order to produce the desired effect, without causing that violent excitement which gained it the name of "laughing gas," it must be administered pure, without admixture of air. In order to do this, a proper

apparatus, with a closely-fitting face-piece, to cover the mouth and nose, must be used. The gas is supplied for use compressed in iron bottles. The bottle is connected with the face-piece by a tube, in the middle of which is an indiarubber bag, differently placed in different instruments. The principle of all is, however, the same, viz., that after the face-piece has been firmly applied, the bag is distended with gas by turning the stop-cock connected with the iron bottle. The patient then breathes the gas from the bag. In some instruments, by an arrangement of valves, the expired gas passes into the air, fresh nitrous oxide being supplied for inspiration. In others the patient breathes backwards and forwards into the bag, inhaling the same gas several times. The former method is preferable, although necessarily causing an increased consumption of gas. In the latter method some gas is lost by escaping from under the face-piece, and its place is supplied by allowing a fresh stream to flow in from the iron bottle. Nitrous oxide is an irrespirable gas, and as no air is mixed with it, the effects produced are, to a great extent, those of asphyxia. It differs, however, from the asphyxia produced by obstruction of the air-passages in this, that the elimination of carbonic acid gas continues to a certain extent, so that although the blood ceases to receive oxygen it does not become overcharged with carbonic acid, and consequently a few breaths of fresh air remove all traces of the temporary asphyxia. The process of anaesthesia by nitrous oxide is not, however, asphyxia and nothing else; a certain proportion of the gas is absorbed, and exerts an influence resembling that of other anaesthetics on the nervous centres. Experiments on animals have shown that, like ether, it always stops respiration before arresting the action of the heart. In the administration of laughing gas the following symptoms are observed. After a time, varying from a few seconds to half a minute, according to the freedom with which the patient inhales the gas, a slight lividity of the face is noticed, and a choking sensation may be felt. In less than one minute, as a rule, this lividity becomes extremely marked, the vessels of the face are injected, there is often some twitching of the eyes and limbs, and the breathing is deeper than natural. At this stage sensation and reflex movements are abolished, and a momentary operation may be performed. Sometimes the patient is conscious that something has been done although he feels no pain, and his ideas are confused. If the operation be more than momentary, the administration of the gas must be continued a few seconds longer. The face then becomes livid, the eyes protrude, the pupils dilate, and the whole appearance of the patient is alarming to an inexperienced bystander. The pulse becomes unsteady, and the respiration slow and stertorous. This is the extreme point to which the administration can be carried, for, as before stated, the gas is irrespirable, and if administered for a sufficient length of time, must necessarily be fatal. Even when carried to this extreme point, however, a few breaths of fresh air suffice to restore the patient perfectly. Occasionally there is some excitement as recovery takes place, but this soon passes off. Vomiting is very rare. During the period of insensibility, and the excitement following it, the patient is very apt to dream; and consequently it is extremely unwise for a medical man to administer laughing gas, or in fact any anaesthetic, to a female patient except in the presence of a third person, as charges of criminal assault have been made under these circumstances, very possibly in perfect good faith on the part of the patient.

Death from the administration of laughing gas has occurred only with extreme rarity. In 1877 it proved fatal to a medical man, apparently from over-distension and paralysis of the right side of a fatty heart, consequent on the obstruction to the pulmonary circulation which always occurs from the partial state of asphyxia which the gas induces. In another case, a patient in the last stage of phthisis failed to rally and died less than one hour after the gas was administered. Several other fatal cases have occurred from the gag used by the dentist breaking or slipping and becoming impacted in the larynx. The only conclusions to be drawn from these cases are, that it is not advisable to give laughing gas in cases of extreme phthisis or fatty heart, and that it is wise for the administrator to have by his side the instruments necessary for the operation of laryngotomy or tracheotomy whenever the operation is one involving the use of a gag. In certain conditions it is said to have caused somewhat serious after-effects. Thus Lafont says he has seen it cause abortion at the fifth month, and the relapse of epilepsy in a boy who had been free from fits for many years. It has also been known to cause a great exacerbation of the disease in diabetes.

Nitrous Oxide and Ether.—As has already been stated, each of these agents possesses certain disadvantages—the anaesthesia produced by nitrous oxide not being sufficiently persistent to admit of the performance of prolonged operations, that of ether being slow of production and often attended by considerable excitement. By the successive administration of the two anaesthetics, these inconveniences are removed, and the advantages of both are secured. The plan adopted by Clover consists in the rapid induction of anaesthesia by the nitrous oxide, and the maintenance of this insensibility by the use of the vapour of ether. In this way one anaesthetic supplements the other, and the rapidity of the one is combined with the persistence of the other.

Ethidene, Amylene, Ethyl-bromide, Chlorethylidene, and various other substances possessing anaesthetic properties have been tried, but have not shown any definite advantages over the agents in common use.

Comparison between Ether and Chloroform.—The history of Anaesthetics furnishes an illustration of the mutability of professional opinion. Ether was the only anaesthetic employed for the first year after the discovery of its use as an anaesthetic. It then so completely gave way to chloroform in this country and generally throughout Europe, that a confusion arose in the public mind as to the real discoverer of Anaesthesia: and Sir James Simpson, who was the first to employ chloroform and to whose energy its general adoption was mainly due, was very commonly considered to be the discoverer of Anaesthetics. In some hospitals, however, and more especially in those of Boston, the birthplace of surgical Anaesthesia, the faith in ether has never been shaken, nor its use abandoned for that of any other agent. In London a change of opinion has taken place, and for the last few years ether has been used as the general anaesthetic, at least in hospital practice and in the hands of special anaesthetists. In Scotland chloroform still remains the agent chiefly in use.

The comparison between ether and chloroform has to be made from three points of view:—1. As to safety: 2. As to convenience: and 3. As to suitability in special cases.

1. *As to safety.*—No anaesthetic is absolutely safe, but with ordinary care and some degree of experience, both ether and chloroform may be administered

with very trifling danger, so trifling indeed, that many a surgeon goes through a long hospital experience without meeting with a fatal case. There are no data at present before the profession from which the relative danger of the two agents can be deduced with anything like certainty, but it is generally acknowledged by those who have much experience of both that ether is safer than chloroform. In University College Hospital ether has been used as the ordinary anæsthetic for many years, yet during that time the few deaths which have occurred during anæsthesia have all been from chloroform. In the hands of an unskilled or careless administrator there can be little doubt that chloroform is more dangerous than ether. It kills more suddenly, and gives less time for restorative measures to be taken. The extreme view taken by some advocates of chloroform, that that agent is absolutely safe if undivided attention be given to the respiration, and that every fatal case is more or less the fault of the administrator from not doing so, may be true of dogs and monkeys, but there is abundant clinical evidence that it is not true of man. There is equally insufficient evidence to justify the opinion of some of the supporters of ether that to give chloroform is so dangerous as to be scarcely justifiable. Both agents are sufficiently safe in the hands of a careful administrator to justify their use, but circumstances may make one or the other preferable. Where no special conditions are present to determine the choice, ether should be preferred as the safer.

2. *As to convenience.*—Chloroform is more convenient than ether in many ways, and, indeed, it was this that led to its general adoption. It can be more easily administered without any special apparatus; it induces anæsthesia more rapidly, and the quantity required is much smaller. These advantages are most important in military and naval practice, where the large bulk of ether required would often render its employment difficult. So, also, in country practice, where Surgeons have often to work single-handed, or with imperfect assistance, chloroform is the more convenient anæsthetic. In hot climates, the extreme volatility of ether makes its use practically impossible. To the patient, chloroform is usually pleasanter, causing less coughing and sense of suffocation.

Under favourable circumstances, however, all these advantages of chloroform over ether disappear. With a proper inhaler anæsthesia is induced as quickly with ether as with chloroform, and can be kept up as easily. The quantity required is not so great as to be an inconvenience in most cases, and all unpleasantness may be avoided by giving laughing gas first. In fact gas and ether is by far the least unpleasant anæsthetic that a patient can take for a major operation. The after-effects of the chloroform and ether are so much alike that on this ground there is little to choose between them. Excitement on recovery is more common after ether. The penetrating and long persistent odour of ether is often very annoying to the patient on recovery, and in this respect it is more unpleasant than chloroform.

During the operation, putting the question of safety on one side, chloroform is undoubtedly more convenient to the Surgeon. Ether frequently causes great venous congestion, and in this way increases the oozing from the wound. It is said, also, to increase bleeding by causing vaso-motor paralysis. It is more difficult to get perfect muscular relaxation with ether, and clonic spasms are not uncommon, which, combined with the violent respiratory movements, are often most embarrassing to the Surgeon.

3. *As to suitability.*—In the majority of cases, chloroform and ether are equally suitable, and the Surgeon must be guided then by the convenience of one or the other, and by his belief as to their relative safety. In certain cases that will be mentioned below, one is preferable to the other.

Choice of an Anæsthetic.—Only the four anæsthetics in common use will be considered here: Laughing Gas, Ether, Chloroform, and the "A. C. E." mixture.

The *Duration of the Operation* influences to some extent the choice of the anæsthetic. For all proceedings not likely to last more than one minute gas should be used, if possible. When it is intended to keep the patient insensible for many hours, as in compression of the aorta for aneurism, chloroform is preferable, ether being inconvenient from the excessive bronchial secretion which it causes.

The *Age of the Patient* is also of importance. In infants and children under seven or eight chloroform is more convenient, and is very safe. Ether, if given without an apparatus, causes more struggling and choking, and if with an apparatus, frightens the child greatly. On the other hand, children take chloroform very well. Some administrators prefer the "A. C. E." mixture, and if the child is very young or weak it is perhaps safer.

In *older children and healthy adults* gas and ether is the pleasantest and safest anæsthetic for all major operations, and gas alone for minor operations of short duration, when these agents can be obtained. In military and country practice and in hot climates there is no doubt chloroform will continue to be the chief anæsthetic on account of its greater convenience; in cities and large towns ether will probably soon become the chief anæsthetic on account of its greater safety. Its use is increasing both in this country and on the continent.

In *aged people* ether is dangerous if they suffer at all from bronchitis and emphysema, and chloroform, which scarcely increases the bronchial secretion, is to be preferred. If the patient is very feeble, the "A. C. E." mixture may be used as being less irritating and depressing. If the lungs are perfectly healthy, ether may be used even in advanced age.

The *Nature of the Operation* has an important influence on the choice of the anæsthetic. In operations about the face, mouth, and throat, chloroform is to be preferred, as it is more easily administered by a tube through the nose and a Junker's apparatus (Fig. 2). In brain surgery chloroform and morphia (p. 31) is always to be used, as the venous congestion that ether gives rise to would be a most serious inconvenience, and the morphia moreover diminishes bleeding by causing some degree of cerebral anemia. Chloroform is, for the same reason, to be preferred in operations about the root of the neck, such as ligature of the subclavian. In any operations about the head or neck in which a cautery is likely to be used, ether must be avoided, as its vapour is explosive. In operations upon the abdominal viscera most Surgeons prefer chloroform, as ether may fail to cause perfect relaxation, and the violent respiratory movements it often gives rise to might greatly embarrass the operator.

In any *Disease of the Lungs* nitrous oxide should be avoided on account of the partial asphyxia induced during its administration, and chloroform or the "A. C. E." mixture is preferable to pure ether, being less irritating. The accumulation of mucus caused by ether is especially dangerous in the

bronchitis and emphyseum of old people, in some cases leading to slow asphyxia a few hours or days after the operation. In these cases no anæsthetic is free from danger, but chloroform is probably the safest.

In *Disease of the Heart*, accompanied by feeble action due to fatty degeneration or dilatation, ether may be used; chloroform, being a cardiac depressant, is dangerous. Ether must, however, be given with caution, as the venous obstruction it sometimes gives rise to may be too much for the feeble heart to overcome. For the same reason, gas is dangerous in such cases. Slight valvular disease of the heart has little influence on the choice of the anæsthetic. If there is reason to believe that there is advanced *arterial degeneration* ether must be given with caution, lest rupture of a vessel in the brain should occur during the stage of excitement: but as the heart in these cases is frequently diseased, chloroform also causes anxiety. It is best, perhaps, under these circumstances, cautiously to give the "A. C. E." mixture.

In *Disease of the Kidneys*, with much albumen in the urine, all anæsthetics are dangerous, especially ether. In *Diabetes* nitrous oxide is said to have caused a fatal exacerbation of the disease. Probably chloroform is the safest anæsthetic in this condition. In *Epileptics* no anæsthetic is free from risk, but from the experience derived from brain surgery, probably morphia and chloroform would be the safest. In *Hysterical, and Insane* patients chloroform, preceded or not by a hypodermic injection of morphia, is probably the best as giving rise to the least excitement. In patients who are under the *influence of opium* it is wiser to give chloroform, as ether under these circumstances might dangerously depress the respiratory centre or choke the lungs with mucus, leading to slow asphyxia before the patient recovered sufficiently from the opium to cough it up.

If, during anæsthesia from ether, it is thought necessary to change to chloroform in order to obtain more perfect relaxation, or on account of very excessive accumulation of mucus in the pharynx and lungs, this must not be done suddenly, lest the already embarrassed heart be brought to a standstill. The patient must be allowed partially to recover and to clear his lungs before the new anæsthetic is given.

The **Administration of an Anæsthetic during Shock** was at one time objected to on the ground that it would still further depress the patient, and that the pain of the operation would be a good stimulus to rouse him. Common sense, as well as experience, are against such an argument. Pain is far more depressing than any anæsthetic. Unfortunately we cannot entirely prevent the additional shock caused by an operation under these circumstances even by anæsthetics, for it is an interesting physiological fact that shock is produced on the system even though the patient be completely anæsthetised. This is particularly noticeable in castration, in which, at the moment when the cord is cut, the pulse falls several beats or stops momentarily, even though the patient be quite insensible. Hence, it may be argued that, although anæsthesia saves the patient that amount of shock which arises from pain, it does not relieve him entirely from the impression produced on the system by a severe mutilation.

As an anæsthetic to be administered during shock ether undoubtedly is preferable to chloroform. Owing to its stimulating action on the heart the pulse will frequently improve during the operation, and it can be pushed to deep anæsthesia without risk. Chloroform, on the other hand, depresses the

heart, and consequently if it is given during shock it is wiser not to push it too far, but merely to benumb sensation without causing complete muscular relaxation.

The **Treatment of the Effects arising from an Overdose of any Anæsthetic** is based on two principles:—1, the establishment of respiration, either natural or artificial, so as to empty the lungs of the vapour contained in the air-cells, and to aid the oxygenation of the blood; and 2, the stimulation of the heart's action, and the maintenance of the circulation.

The treatment to be adopted on the occurrence of dangerous symptoms, or of apparent death from chloroform, is as follows:—

1. The administration of the vapour must be at once discontinued.

2. The tongue should be seized with the fingers, or with forceps, and drawn out of the mouth: and the larynx pushed up so that the glottis may be opened. The tongue must be pulled forcibly forwards, not merely pulled out of the mouth, for the reasons before stated. The finger should be immediately passed down the throat and the glottis examined for the possible presence of vomited food. The pharynx should be freed from mucus with a sponge on a holder.

3. Fresh air should be admitted to the patient by opening doors and windows, and by preventing bystanders or spectators from crowding round.

4. All constrictions should be removed from the patient's throat and chest, and these parts should be freely exposed.

5. Artificial respiration must *at once* be set up, whilst these other measures are being carried out. This should be done by the Sylvester method, which is fully described in the chapter on Asphyxia. Artificial respiration should be commenced by a forced expiratory movement, so as to empty the lung as far as possible of the anæsthetic vapour. Milne Murray has shown that rabbits can be revived from a nearly fatal dose of chloroform with much greater certainty if, as the first step, before commencing artificial respiration, the lungs are exhausted as far as possible by aspiration. To attempt to adopt this plan in man would cause serious loss of time before commencing artificial respiration.

6. Electricity, in the form of faradisation of the phrenic nerve, has been of great use in some cases as an adjunct to artificial respiration. It must be applied methodically as described under the treatment of asphyxia. In using electricity care must be taken not to stimulate the vagus, the effect of which might be finally to inhibit the feeble heart.

7. Nitrite of amyl, when inhaled in health, causes, according to Branton, flushing of the face, throbbing of the carotids, and a quicker and fuller pulse, with quickened respiration. It causes diminished blood pressure by a general dilatation of the arterioles, and thus relieves the heart. It seems, therefore, from its stimulating influence on the cardiac and respiratory centres, to be indicated as an antidote in chloroform poisoning, whether of the syncopal or asphyxial form: the inspiration of the vapour of ten to fifteen drops of the nitrite unloading the vessels and restoring the heart's action. The administrator should always have at hand, in case of accident, some glass capsules of nitrite of amyl. One of these should be broken into a handkerchief and held over the face while artificial respiration is continued as above described. The hand should be placed at the same time as low as possible.

8. As accessory means, friction of the extremities may be employed; a little brandy should be rubbed inside the mouth; and cold water dashed on the face.

9. Tracheotomy or laryngotomy is necessary when the asphyxia is due to the impaction of some foreign body, as false teeth or a gag in the larynx during insensibility, or to accumulation of blood in the pharynx or trachea. It may also be of use when, owing to emphysema of the lungs and rigidity of the chest-wall, artificial respiration cannot be efficiently carried out, but it will be necessary then to blow the air into the lungs and suck it out through the tube either by bellows or by the Surgeon's mouth.

LOCAL ANÆSTHESIA.

Local anæsthesia may be induced in two ways: 1, by cold, and 2, by the use of cocaine.

COLD.—The application of ice and salt, as introduced by J. Arnott, may conveniently be employed in many cases in which general anæsthesia is inadmissible or inconvenient. Local anæsthesia can be produced only in those cases in which the incisions merely implicate the skin and subcutaneous structures, as in opening abscesses, slitting up sinuses, avulsion of toe-nails, or removing small superficial tumours. For such purposes, however, it is extremely valuable. The mode of using the *frigorific mixture* is as follows: About a tumblerful of rough ice is put into a strong canvas bag, and finely powdered with a mallet. It is then poured out on a plate, and half its bulk of salt is quickly mixed with it by means of an ivory or wooden paper-knife. The mixture is then put into a muslin or gauze bag and applied to the part for from five to ten minutes. As soon as the skin becomes white and hard, the incisions may be made without any pain being experienced. The frozen part speedily recovers, no inconvenience resulting.

The **rapid evaporation of highly rectified ether** has been applied by Richardson in the production of cold sufficient to freeze a part, and thus render it temporarily insensible. A fine spray-jet of ether of a low specific gravity is thrown upon the part to be anæsthetised. The skin rapidly becomes white and hard—is, in fact, frozen. This method of inducing local insensibility to pain is more exact and efficacious than that by the *frigorific mixture*, and is generally preferred. It is applicable in the same class of cases. The ether should be tested before it is used by pouring a little into the hollow of the hand, where, if it is of the proper quality, it will boil violently.

COCAINE is an alkaloid extracted from the leaves of *erythroxylon coca*. Coca has been known in Europe since the discovery of Peru, the natives of which country have from time immemorial been in the habit of chewing the leaves for the purpose of allaying hunger and supporting strength during prolonged physical exertion. The alkaloid was first extracted by Niemann in 1859, and both he and Hughes Bennett, who investigated its properties in 1872, pointed out the fact that it causes numbness when applied to mucous membranes. No practical use was, however, made of this discovery till 1884, when Carl Koller, of Vienna, demonstrated that the eye could be rendered sufficiently anæsthetic for the performance of almost any operation by putting a few drops of a solution of cocaine on the conjunctiva. The value of this

method was at once recognised, and at the present time cocaine has to a great extent replaced general anæsthetics in ophthalmic surgery. Its use was soon extended to other mucous membranes, and subsequently, by means of hypodermic injections, to the skin and subcutaneous tissue.

Cocaine is most commonly used in the form of a solution of the hydrochlorate in distilled water. The solution should be sterilized by boiling, and kept in a carefully stoppered bottle, otherwise fungoid growths are apt to develop in it. Cocaine can be kept in 1 grain powders which may be dissolved in 10 minims or more of water when required for use. The water must be previously boiled if the solution is to be injected hypodermically.

Cocaine causes a contraction of the small arteries of the part to which it is applied, and thus greatly diminishes the bleeding during an operation, such as removal of a polypus from the nose.

Mode of Employment.—*For the eye*; two or three drops of a 4 per cent. solution are dropped upon the conjunctiva. This is repeated in from three to five minutes, and after about the third application the conjunctiva will be found to be insensible when touched with the finger. The anæsthesia extends to the deeper structures of the eye, so that the operation for cataract or an iridectomy can be performed without appreciable pain. The anæsthesia is accompanied by dilatation of the pupil.

For the mouth or throat.—A 10 or 20 per cent. solution is applied by means of a camel's hair pencil or by a spray apparatus. The anæsthesia commences in about three minutes, and if the application be repeated at intervals becomes complete in from ten to twenty minutes. It passes off in from half to three-quarters of an hour.

For the urethra a 10 per cent. solution is best. It may be injected either directly with a syringe or by means of a catheter to the deeper parts or into the bladder. Its effects are not very certain, as it is difficult to apply it thoroughly to the whole length of the canal, and in the bladder it is apt to be diluted by the urine or prevented from coming in close contact with the mucous membrane by a layer of mucus.

For the removal of small tumours or other minor operations on the skin or subcutaneous tissue it must be applied by hypodermic injection. From 4 to 5 minims of a 4 per cent. solution must be injected at several points in the area which it is desired to render anæsthetic. Anæsthesia is complete in from two to five minutes. This can be ascertained by gently pinching the part with a pair of forceps. It commonly lasts from ten to fifteen minutes. If sensation returns during the operation a few drops of the solution may be poured into the wound, and after a couple of minutes' delay the performance may be continued. If the operation is upon one of the limbs, the duration of the anæsthesia may be greatly prolonged by the application of a tourniquet after one or two minutes have been allowed for the diffusion of the solution. The same effect may be produced, less perfectly, in other parts by surrounding the anæsthetic area with a ring of wood or metal and pressing it firmly down so as to limit the diffusion of the solution.

Cocaine Poisoning.—Several cases have been recorded in which unpleasant and sometimes even alarming symptoms have followed the use of cocaine. The dose in these cases has been very variable, in some little more than a grain of the hydrochlorate. The most common of these effects have been temporary giddiness and nausea, with a sense of oppression on the chest and

a rapid pulse; these soon pass off and leave no evil effects behind. In more extreme cases, after larger doses, there have been marked pallor of the face, dilated pupils and syncope followed by great prostration on recovery. In one case the patient complained of being unable to see for some hours, and in two, articulation was indistinct for some time. The instances in which these unpleasant consequences have been observed are not yet sufficiently numerous to make it possible to state accurately under what conditions they occur or what is the limit of safety in administering the drug. In one case of extensive tuberculous disease of the kidneys and bladder, 20 grains accidentally given as a draught proved fatal in about one hour. In a case of attempted suicide, 23 grains were taken internally without serious consequences; and, on the other hand, Mayo Robson records a case in which a middle-aged gentleman became aphasic and unable to write half-an-hour after a solution containing one grain had been injected into the nose before the removal of a polypus. The sense of oppression on the chest and the cardiac disturbance are relieved by the inhalation of nitrite of amyl. Alcohol and subcutaneous injections of ether may be given to relieve the faintness.

PERFORMANCE OF AN OPERATION.

In the performance of an operation in private practice the Surgeon must see for himself that the preparations are properly made. The room must be well lighted, of sufficient size and properly warmed. Whenever it is possible the patient should be placed upon a table. An ordinary bed is too low, and its width makes it difficult for both the Surgeon and his assistant to be within easy reach of the wound. The table upon which the patient is placed must be of the ordinary height. The strong deal table usually found in kitchens answers the purpose fairly well. It must be steady on its legs, and if it is not more than three feet wide it will be more convenient. It must be covered with a blanket folded into four layers; another blanket must be provided to place over the patient's body, and pillows must be comfortably arranged for the head. A tray filled with saw-dust, or an old blanket folded very thickly, may be placed on the floor to catch the blood. The friends must be asked to provide in the room a dozen towels, four washing-basins, and two large cans, one of hot and one of cold water, and a slop-pail or foot-bath. A gallon or more of an antiseptic solution, such as carbolic acid lotion of the strength of 1 in 20, should be in readiness, which may be diluted to 1 in 40, for washing the sponges. The necessary amount of the antiseptic solution, according to the extent and nature of the operation, must first be prepared, and the cans of common water must then be removed to one corner of the room, and orders given to the nurse not to touch them: for, unless she is thoroughly experienced, she is almost certain to use plain water instead of the antiseptic fluid during the excitement of the operation.

The sponges should be brought by the Surgeon himself, and should be properly prepared. Improperly-cleansed sponges have always been justly considered a potent source of infection in wounds. New sponges are apt to be gritty, and should be soaked in a dilute solution of hydrochloric acid for at least twenty-four hours, after which they must be carefully washed. They should then lie for at least twenty-four hours in a 1 in 20 solution of carbolic acid. They must then be squeezed as dry as possible, and put in a glass

vessel covered with a lid to keep out the dust. Before being used they should be again soaked for some hours in carbolic lotion. After an operation the meshes of a sponge are more or less filled with coagulated blood, which mere washing in water will hardly remove. In order to clean it thoroughly, it may be soaked in a strong solution of sulphurous acid; or, after maceration for forty-eight hours in a dilute solution of hydrochloric acid (about ten drops of the strong acid to the ounce of water), and for twenty-four hours in a strong solution of carbonate of soda, it may be well washed in common water, and kept ready for use in a bath of 1 in 20 carbolic acid lotion. A simpler plan, and one which experience has shown to be very efficient, is to wash the sponges for ten minutes in very hot water with a large amount of soft soap. The soap must be well washed out by repeated rinsing in fresh hot water, after which the sponges may be placed in the carbolic lotion. In many cases sponges are advantageously replaced by pieces of salicylic or sal-alembroth wool moistened with some antiseptic solution and squeezed as dry as possible.

Before commencing an operation, the Surgeon must look over his instruments, comparing them, if the operation be complicated, with a list previously made out; he must see that they are arranged in the order in which they are wanted. They should be placed in a flat dish filled with an antiseptic solution. For this purpose nothing is better than a 1 in 20 solution of carbolic acid, which has no injurious effect on the instruments. This method of sterilizing the instruments seems practically efficient, but some Surgeons prefer to expose them to super-heated steam in a specially constructed chamber, and use knives with metal handles which will not be injured by the heat. Much of the successful performance of an operation depends on the attention and steadiness of the assistants. Of these there should be enough, but not too many. In all capital operations three or four will be required: one for the administration of the anæsthetic, another to command the artery, a third immediately to assist the Surgeon, and the fourth to hand sponges, instruments, &c. The duties of the assistants should be performed in silence, and each man must carefully attend to his own business, and not neglect this, as is too often done, in his anxiety to see what the Surgeon is about. There should be no unnecessary talking when once the patient is on the table; the Surgeon's directions ought to be conveyed by a brief word or two, or by a sign with the hand.

The incisions for the operation should be carefully and properly planned, so as to give sufficient space with as little mutilation as possible; but it must always be borne in mind, that although a needlessly long incision may lead to unnecessary disfigurement, it does not add materially to the danger of the patient, while too small an incision hampers the Surgeon and greatly increases his difficulties, especially in the arrest of hæmorrhage.

Incisions may be made by cutting from without inwards, or from within outwards, or simultaneously. The most convenient instrument for all ordinary

Fig. 3.—Right hand held peculiarly.

incisions is the scalpel. This should be set on a smooth ebony handle, which is less slippery than ivory or steel when wetted with blood, and admits greater delicacy of touch; it should be light in the blade, nearly straight-backed, and slightly belled in the cutting edge. The beel should be as wide as the widest part of the blade, and there should be no constriction where it joins the handle. When very free and extensive incisions are required, as in the removal of large tumours, a Liston's bistoury, of proper size and shape, is a very convenient instrument (Fig. 3). For a subcutaneous incision, a very small narrow-bladed knife is required.

The ordinary scalpel is held in two ways: first, like a pen (Fig. 4): secondly,

Fig. 4. — Scalpel held like a pen.

like a dinner-knife (Fig. 5). The former position is that universally adopted in dissecting the dead body, and the habit of always holding the knife in this way is one of the first faults which a student commencing operative surgery has to correct. In dissection, also, the student habitually turns his knife from

Fig. 5. — Scalpel held like a dinner-knife.

the deep parts towards the skin, so that any slip of the knife may not injure the subcutaneous structures which it is his object to preserve. In raising flaps in the living body, the reverse must be the rule, as, if the skin and subcutaneous tissues are scored by the knife, the flap will certainly slough. Every teacher of operative surgery has experienced how difficult it is to correct this most dangerous habit in young operators. In making an ordinary incision from without inwards, as in the removal of a tumour, or in cutting down upon an artery in its continuity, the skin must be put gently on the stretch, and the knife entered perpendicularly (Fig. 3), so as fairly to penetrate the subcutaneous fat: the handle may then be lowered, so that the incision is continued with the belly of the knife. This may be done by drawing the knife steadily along, if the edge is good and the tissues are not particularly resistant: more often, however, a slight rapid sawing movement is required. In bringing

the knife out again, the handle should be raised so that there may be no "tailing," but that the incision may be as nearly as possible of equal depth throughout. The bad habit of gradually losing length as the incision is deepened, so that, for example, a four-inch incision through the skin is reduced to three at the fascia, should be carefully avoided. An ordinary wound is gradually deepened by simply drawing the knife along it, with its edge directed downwards and parallel to the incision, until the deep fascia is reached. As the wound is deepened it is, if necessary, held open by an assistant with blunt hooks or spatulæ. The division of the deep fascia often requires care, as important structures may lie beneath, which it is necessary to avoid. It is done therefore in one of two ways. It may be picked up with a pair of dissecting forceps, and a small hole carefully made in it, through which a

Fig. 6. — Division of the fascia on a director. Blunt hooks holding open the wound.

director may be inserted, upon which it may be divided, the back of the knife being turned downwards (Fig. 6) ; or, the small hole having been made in it, the point of one blade of the forceps may be introduced, and the fascia seized and raised slightly from the parts beneath. The side of the knife then being turned downwards, the portion of fascia raised in the forceps is divided in the direction of the incision in the skin, only the last half-inch of the knife being used. A fresh hold is then taken with the forceps, and another piece of the fascia divided in the same way (Fig. 7). With a little practice it is easy in this way to make a clean linear incision through the fascia. It is a much safer plan than that of using a director, as nothing is divided but that which is raised by the forceps, whereas in pushing a director blindly under a fascia its point may pass beneath something which it is not intended to cut.

Where the tissues are very lax beneath the fascia, it is often a convenient plan to guide a probe-pointed bistoury on the forefinger of the left hand, instead of using a director. The finger is the best director when it can be used, as it can be guided more or less by sensation. Occasionally in deepening a wound through very loose structures, amongst which important vessels may lie, as in removing tumours from the root of the neck or the axilla, the Surgeon may prefer to make use of a blunt instrument, and to tear the tissues instead of

Fig. 7.—Dissection through a fascia. Spencer Wells's forceps on a bleeding vessel. Blunt hooks holding open the superficial wound.

cutting them. With this view he may use two pairs of forceps, or one pair of forceps and a director, or the handle of the scalpel. He must not, however, be tempted to use these forcibly or rashly, as by so doing much mischief may be produced. He must work methodically, picking up what he intends to tear with the forceps, and being careful to tear only what he has thus seized. In some cases a properly cultivated finger-nail or thumb-nail will be found a most useful instrument.

PREVENTION OF HÆMORRHAGE DURING OPERATIONS.

In every operation involving the use of the knife, loss of blood is the primary danger to be guarded against. This may be prevented most conveniently in the extremities by the use of the tourniquet or the elastic band, or by an assistant compressing the main artery of the limb. If the seat of the operation be such as not to admit of this, the assistant may compress the bleeding vessels as they are divided during the operation; and as soon as it is

concluded, he can remove his fingers from them, one by one, to admit of their being ligatured or twisted. This plan has, however, the disadvantage of occupying the assistant's hands at a time when they may be wanted to help the Surgeon, and it will be found more convenient if the vessels be seized in a pair of catch-forceps of the pattern recommended by Pean and Sir T. Spencer Wells (Fig. 7). These forceps have scissor handles, and the grasping extremity is roughened by rather deeply cut transverse teeth. They can be applied instantaneously, and their hold is extremely firm, and from their length and weight it is easy for the assistant to keep them out of the wound during the operation, while at the same time his fingers are free to help the operator. At the conclusion of the operation, it will frequently be found that their pressure has permanently arrested the bleeding from the vessels to which they have been applied. Their action in this respect will be more fully described in the chapter on the Arrest of Hæmorrhage. As a means of temporarily arresting bleeding during an operation, they have proved of the greatest possible value, especially in operations about the head and neck, and abdomen.

The Tourniquet and its Application.—The older Surgeons from the time of Archigenes, a Roman who lived in the first century, bound a tight narrow band, called the "fillet," round a limb during an amputation. The fillet was intended to serve three purposes—first, to steady the muscles during the incision; secondly, to numb the limb; and thirdly, to arrest the flow of blood; but it seems to have but imperfectly succeeded in producing the desired results. In 1674, Morel, a French Surgeon, improved the fillet by introducing a piece of stick beneath the band, by means of which it could be twisted up and efficiently tightened. To protect the limb from being bruised, he introduced compresses beneath the band; and to ensure the more complete compression of the main artery, he placed a rolled bandage along its course. Beneath the knot, to save the skin from being pinched, he placed a piece of leather or thick paper. To this apparatus, he gave the name of "tourniquet." The tourniquet in this primitive form is still useful, in the absence of any other appliance, for the temporary arrest of hæmorrhage. A round pebble, or any hard body about the size of a hen's egg, may be rolled in the middle of a pocket-handkerchief and laid over the artery, the ends of the handkerchief being knotted round the limb, and then twisted up tightly with a piece of stick. In the hands of an ignorant person, however, the pebble would be better left out, as if it were not applied in the proper place, it might serve merely to relieve the main artery from pressure. The piece of folded paper beneath the knot should never be omitted, or the agony caused by the pinching of the skin would be more than the patient could bear.

The screw tourniquet which replaced Morel's imperfect apparatus, was invented by the French Surgeon Petit in 1718; and, although the details of its mechanism have undergone improvements, the instrument used in the present day is essentially the same (Fig. 12). It may be applied with or without a pad over the artery. If a pad be used, it is best made of a common roller, from two and a half to three inches wide; of this a few feet must be unrolled. The roller is then placed longitudinally on the artery, and the unrolled part carried twice round the limb so as to keep the pad in position, but care must be taken in doing this not to constrict the part sufficiently to cause venous engorgement. The tourniquet is then applied, and the band

buckled with sufficient tightness to keep it in its place ; but the instrument should not be screwed up until the moment of the operation. It should then be tightened rapidly, so as to avoid as much as possible the congestion of the limb that always occurs when a tourniquet is applied. The first effect of the tightening of the tourniquet is to compress the large veins ; the second, to arrest the flow of blood through the arteries : hence the more slowly it is screwed up the greater will be the venous engorgement of the limb. The blood that flows from the limb during an amputation, when the tourniquet is applied as above described, is almost entirely venous, coming from the lower part of the member.

A screw tourniquet may be equally well applied without a pad (Fig. 12) ; but it is then necessary to put a piece of card, folded paper, or leather, beneath the screw to save the skin from being pinched. The pad has the disadvantage of being liable to slip, and if not very accurately applied, it tends rather to protect the artery from pressure than to compress it. The screw tourniquet is now almost abandoned in favour of the simple elastic band. It is, however, a

Fig. 8. Esmarch's Tourniquet applied to Shoulder.

useful instrument when the Surgeon is short of skilled assistants, and especially in wounds of large arteries, in which an occasional relaxation of the tourniquet is required to guide the operator to the injured vessel.

Compression by Elastic Tubing or Bandage.—The circulation through a limb may be completely arrested by two or three turns of an elastic bandage applied with moderate firmness. The bandage may then be secured by a knot or by a pin. During the Franco-German War, the field tourniquet served

out to the German army consisted of nothing more than a narrow elastic bandage about one inch in width and three feet long. Esmarch, of Kiel, introduced as a substitute for the bandage, a piece of india-rubber tubing about three-quarters of an inch in diameter and two feet in length, having a hook fixed to one end and an eye to the other. This is stretched and wound firmly and rapidly round the limb two or three times. It often happens that the hook does not meet the eye exactly as it is wanted to, so that either an extra turn of the tube must be put round the limb, or the former turns must be unduly relaxed. This may be obviated by replacing the hook and eye by two pieces of stout tape, bound on to the ends of the india-rubber tube. The tube can then be applied with exactly the amount of force required, and secured by tying the ends of the tape together. It must be remembered that in applying the band, enormous pressure is easily obtained by a few turns one over the other, so much so, that in situations in which the chief nerves lie very close to the bones, as in the arm, symptoms of paralysis, sometimes lasting for weeks, are recorded as having resulted from its use. Such accidents are more likely to occur if the narrow tube is used, than if the constriction be made by an elastic bandage. The latter should therefore be preferred where it can be conveniently applied.

In certain regions special plans have to be adopted in the application of the elastic tourniquet.

In excisions or amputations of the **shoulder**, the india-rubber tube must be very forcibly stretched and applied round the shoulder, the lower part of the turn being high in the axilla, so as to compress the artery against the neck of the scapula, and the upper part as far as possible internal to the end of the clavicle and the acromion process. To prevent its slipping, a piece of bandage should be put beneath it both in front and behind at the time it is applied, by means of which an assistant may hold it in position (Fig. 8).

In operating upon the **upper part of the thigh**, the india-rubber tube must be of sufficient length to go round the limb and the pelvis. The middle of the tube is to be applied to the front of the thigh immediately below the groin: the two ends are then to be carried forcibly round and brought up to the front again, where they cross, and are afterwards passed round the pelvis immediately below the crest of the ilium (Fig. 9).

In amputation at the **hip-joint**, a long piece of bandage must be laid upon the middle of the groin in the line of the limb, and a similar piece behind, over which the tube is to be applied, so that by pulling on the ends of the bandage any slipping of the band may be prevented during the operation. The middle of the tube is to be placed in the perineum, and the ends pulled forcibly outwards and crossed as high above the trochanter as possible, and afterwards carried round the pelvis immediately below the crest of the ilium (Fig. 10). If the bandage is applied with sufficient force, it is unnecessary to put a pad over the

Fig. 9. - Esmarch's Tourniquet applied to Thigh.

Fig. 10. - Arrest of Hemorrhage in Operations on the Hip-joint. The dotted line is the position of the bandage for the amputation at the hip-joint.

Fig. 11. - Esmarch's Band applied for Operations on the Penis or Scrotum.

artery. In Fig. 10 the patient is lying on his side with the right thigh flexed, in the position for an oval amputation at the hip-joint.

In operations upon the **penis or scrotum**, a piece of bandage should be laid along the spine behind and brought forward to the scrotum in front.

The middle of the tube is then placed in the perineum, and the lower end of the bandage turned up over it. The ends of the tube are next brought forwards forcibly, crossed on the pubes, and afterwards carried round the pelvis, passing on each side mid-way between the trochanter and the crest of the ilium. The two parts of the bandage are then tied together, thus attaching the loop of the tube surrounding the scrotum to the part which passes behind; any slipping of the tube during the operation is thus rendered impossible (Fig. 11).

Bloodless Methods.—Various devices have been employed to diminish the loss of blood during operations on the extremities, and at the same time to get rid of the blood which otherwise fills the wound, and more or less conceals the steps of the operation, even when a tourniquet has been applied. The oldest of these is bandaging the limb firmly up to the level at which the tourniquet is applied, before tightening the screw. This is not very efficient, especially when a pad is placed over the main artery beneath the band of the tourniquet. Lister has shown that the limb may be rendered bloodless by simply elevating it as high as possible for about one minute, and then rapidly applying an elastic band or a screw tourniquet without a pad. To hasten the emptying of the blood-vessels the limb may be rubbed firmly in the direction of the circulation (Fig. 12). By experiment he has further shown that this is brought about not only by the emptying of the veins, but by the contraction of the arteries which occurs when the limb is placed in the elevated position. Esmarch has obtained the same result by applying an elastic bandage spirally from the distal extremity of the limb upwards to the point at which the tourniquet or elastic band is applied (Fig. 13). On removing the elastic bandage from below the tourniquet, the limb will be found to be absolutely bloodless, even the bones very frequently yielding no blood on being cut. With the exception of the elasticity of the skin and the retraction of the muscles, the operation now resembles one on a dead body. In this state, all vessels of any size can be seen and tied before the tourniquet is removed. The

Fig. 12.—Lister's Method.

anæmia thus induced is followed on removing the tourniquet by hyperæmia, corresponding in intensity to the time that the limb has been kept bloodless, and very free oozing consequently sets in, which often takes some time to arrest by means of cold and exposure to the air. Thus it may happen that the patient loses as much blood as if Esmarch's method had not been employed. Esmarch, however, subsequently adopted a plan by which most operations on the extremities can be rendered actually bloodless. He first secures every vessel visible on the surface of the wound, and then, having put in the drainage-tubes and introduced the sutures, he applies a dressing com-

posed of antiseptic gauze surrounded by cotton-wool impregnated with salicylic acid, which is moderately firmly bandaged to the part. The limb is then placed in an elevated position, and finally the elastic tourniquet is removed. The elevated position is maintained for at least half an hour or an hour. In 12 cases of amputation and 56 excisions in which this plan was tried, it succeeded perfectly. In 118 operations for necrosis, it was necessary to remove the dressing on account of hæmorrhage in six cases only.

Various objections besides the subsequent oozing have been raised to Esmarch's bloodless method. It has been stated that it causes sloughing of the flaps and increases the tendency to secondary hæmorrhage after large amputations, by unnaturally augmenting the proportion of blood in the body, and so giving rise to increased arterial tension. Neither of these statements is supported by experience. A more rational objection against it is, that when the limb is infiltrated with the products of inflammation, or when perhaps clots exist in the veins, these may be driven on into the circulation by the application of the elastic bandage. Although no case of such an accident has been recorded, it would be safer when such conditions exist to empty the limb of blood by the simpler plan of elevation as before described. The same plan is also better employed in cases of cancer or sarcoma, in which the danger of

Fig. 15.—Esmarch's Method.

dislodging particles and driving them into the circulation would be very considerable. The advantages of the bloodless method of operating, however, especially in diseases of bones and joints, far outweigh any supposed disadvantages.

It is difficult to say how long complete arrest of the circulation through a limb may be maintained by the elastic band or the tourniquet without danger of gangrene. It must necessarily vary according to age. Esmarch's method has been used for about three hours without any evil result.

Compression of the Main Arterial Trunk is in the present day employed only as a temporary expedient before a tourniquet can be applied, or immediately after its removal, while a few vessels before invisible are being secured, or in those situations in which the application of a tourniquet is impossible. It is far safer to trust to an instrument than to the hands of an assistant, however steady and strong. When the tourniquet is applied with sufficient tightness, the whole circulation through the limb is arrested; but this can never be done by the compression of the main trunk alone, as the collateral vessels still convey blood into the limb. Then again, if the operation be unexpectedly protracted, the fingers of an assistant may tire, and the steadiness of their pressure be relaxed. For these reasons Surgeons invariably employ the tourniquet in amputations; and even Liston, who at one period of

his career discarded this instrument, commonly employed it during the latter years of his life.

The points chosen for the compression of arteries are those at which the vessel is comparatively superficial, and is placed over some bone against which it can be pressed. The following are the chief arteries which the Surgeon may be called upon to compress :—

The **common carotid** can be felt pulsating in front of the sterno-mastoid, and is best compressed by pressing the thumb directly backwards towards the vertebræ opposite the cricoid cartilage (Fig. 14). To steady the hand, the fingers should grasp the back of the neck. If the pressure be applied below the transverse process of the sixth cervical vertebra, the vertebral artery will be compressed at the same time as the carotid.

The **facial artery** is easily compressed against the jaw, where it lies quite superficially immediately in front of the anterior border of the masseter. The fingers may be placed on the opposite side of the jaw to steady the hand, and if necessary, the forefinger may compress the opposite artery. In operations

Fig. 14.—Compression of the Carotid.

Fig. 15.—Compression of both the Facial, right Temporal, and right Subclavian Arteries.

upon the nose and lips the assistant may stand behind the patient and compress both vessels while he holds the head (Fig. 15).

The **temporal artery** is compressed where it can be felt pulsating immediately in front of the ear (Fig. 15).

The **subclavian artery** may require compression in the third part of its course in operations in the axilla, or on the shoulder-joint, or in amputations high up in the arm. If digital compression be attempted the fingers should be placed behind the lower part of the neck, with the palm of the hand on the ridge formed by the trapezius. The thumb is then forcibly pressed upon the artery, where it lies on the first rib, immediately external to the outer border of the sterno-mastoid and opposite the most prominent part of the clavicle (Fig. 15). As considerable force is required efficiently to compress this artery, the fingers of the opposite hand may be pressed upon the thumb which is upon the vessel. The patient's head should, if possible, be inclined towards the side on which the artery is being compressed, so as to relax the cervical fascia. As force required is often so great that the assistant is apt to become fatigued by his pressure, it is better to compress the artery with some mechanical device. The most commonly employed is a large door-key. The ring of

the key is wrapped round with a strip of lint, so as to prevent it from injuring the patient: the other end is also well padded to protect the Surgeon's hand. The padded ring is then pressed forcibly down upon the artery in the situation before described (Fig. 16).

In cases in which the clavicle is pushed up by an aneurismal tumour, Syme recommended that an incision should be made above the clavicle through the skin and deep fascia, so that the fingers of the assistant might bear almost directly upon the vessel, which would thus be more securely compressed.

The **brachial artery** is best compressed by grasping the limb opposite the middle of the arm, so that the tips of the fingers are placed immediately internal to the edge of the biceps, and thus press the artery against the bone while the thumb rests against the humerus on the opposite side (Fig. 16).

Fig. 16.—Compression of Subclavian with key, and Digital Compression of the Brachial.

The **radial and ulnar arteries** frequently require compression while the Surgeon is searching for a wounded vessel in the palm of the hand: and the assistant must, under these circumstances, steady the hand as well as compress the vessels. He will best do this by grasping the lower part of the forearm firmly with both hands, his fingers being at the dorsal aspect, and his thumbs pressed upon the arteries immediately above the wrist: on the radial, at the point at which it is commonly felt as the pulse, and on the ulnar, at the outer border of the tendon of the *flexor carpi ulnaris* (Fig. 17).

Fig. 17.—Compression of the Radial and Ulnar Arteries.

Compression of the abdominal aorta is required in some cases of amputation at the hip-joint or high up in the thigh, and in operations for aneurism of the iliac arteries, or the branches of the internal iliac in the buttock. The point at which it is most conveniently compressed is immediately above its bifurcation. The bifurcation of the aorta takes place on the body of the fourth lumbar vertebra, a little to the left of the middle line: superficially this corresponds to a point a little below and to the left of the umbilicus, and on a level with the highest part of the iliac crest. In compressing the aorta, therefore, the pressure should be applied a little above and to the left of the umbilicus. In children, and very thin subjects, the aorta can usually be compressed with the hand in this situation, but the force required is so great that it is impossible for it to be maintained for any length of time. In the absence of any other instrument, Eschmarch recommends the following plan:—A common roller bandage about two and a half inches wide and eight yards long is to be rolled round a stick about the thickness of the

thumb and nine inches long. The pad thus formed is held in the proper position by the ends of the stick, while several turns of elastic bandage are passed round the body so as to press it forcibly against the spine. After it is applied an assistant must continue to hold the pad in position by means of the stick. An objection common to this and to all other elastic appliances for compression of the aorta is, that should the patient vomit, the forcible contraction of the abdominal muscles will lift the pad from the aorta and relax the compression. It is better, therefore, whenever possible, to use the instrument known as Pancoast's or Lister's Aortic Tourniquet (Fig. 18). This consists merely of a large horse-shoe clamp, one end of which is expanded and padded so as to fit the spine, and the other receives a screw which presses down a pad of sufficient size to compress the aorta with certainty. Lister states,

Fig. 18.—Lister's Aorta Compressor applied.

that from examination of a considerable number of bodies, he has found that the aorta is as often in the middle line as to the left of the spine, and consequently it is better always to feel for the pulsation before applying the pad, taking the highest point of the crest of the ilium as the level of the bifurcation, and ignoring the umbilicus altogether. If the pad be placed exactly on the vessel, a comparatively slight degree of pressure is required to arrest the flow of the blood, but should it be misplaced the Surgeon may be tempted to use an amount of force

which might prove injurious to the soft parts and intestines beneath the pad. In order still further to avoid injury to these parts, it is as well to place a soft hollow sponge beneath the pad. The instrument, when properly applied, interferes but slightly, if at all, with the flow of blood through the vena cava.

Compression of the common iliac may easily be carried out by the application of the aortic tourniquet over the line of the artery: that is to say, in the upper third of a line drawn from a little to the left of the umbilicus at the level of the highest point of the crest of the ilium to a point midway between the symphysis pubis and the anterior superior iliac spine. Richard Davy, of the Westminster Hospital, has invented a plan of compressing this artery by means of a straight lever of wood introduced into the rectum, which usually answers very well. The lever should be about two feet in length, smooth and round, and shaped something like a poker. About two ounces of olive oil having been injected into the rectum, the end of the lever is introduced to such a distance that its point comes to lie over the artery in the groove between the last lumbar vertebra and the psoas muscle. By raising the handle of the lever and bringing it against the opposite thigh, the artery is most efficiently compressed, the tissues of the perineum acting as the fulcrum.

Compression of the external iliac can be carried out with certainty only immediately above the groin, as above that point it is easily pushed over the brim of the pelvis into such a position as to escape pressure. If it be desired to compress it, this may be done either with the fingers or by placing a roller

bandage across the line of the artery, and securing it first by a few turns of a common bandage, passing in a figure-of-eight round the upper part of the thigh and the pelvis below the crest of the ilium, over which must be put a few turns of an india-rubber bandage.

Compression of the femoral artery immediately below the brim of the

Fig. 19. — Pressure with Thumbs. Application of Tourniquet to Femoral Artery.

pelvis (Fig. 19) is commonly resorted to for the temporary arrest of hæmorrhage from any part of the lower limb. The Surgeon stands by that side of the patient on which the vessel is to be compressed, with his back towards the patient's head and his body inclined over the pelvis. He then grasps the limb firmly with both hands, the fingers of one hand obtaining a hold on the mass of the adductor muscles, and those of the other on the posterior border of the trochanter major. His two thumbs are placed one over the other upon the artery at a point immediately below Poupart's ligament, and exactly midway between the symphysis pubis and the anterior superior iliac spine. Instrumental compression in this situation is employed only in the treatment of aneurism, and will be described with that disease.

The popliteal artery is too deeply situated to be compressed with advantage. In bleeding from a point below the knee and above the ankle, it is better to apply the pressure to the femoral artery at the groin.

The anterior and posterior tibial arteries at the ankle may conveniently be compressed during an operation on the foot (Fig. 20). The assistant may,

Fig. 20. — Compression of Tibials, and mode of holding the foot in operations requiring an incision in the sole.

at the same time, steady the foot, and hold it in a convenient position for the Surgeon. The limb being bent at a right angle, the assistant puts the patient's knee in his axilla; he then grasps the limb firmly with one hand above the ankle, and with the finger and thumb compresses the vessels. The posterior tibial is to be compressed with the tips of the fingers one finger's breadth behind the internal malleolus, and the anterior tibial with the thumb in front of the ankle at a point exactly midway between the two malleoli, that is to say, a little to the outer side of the middle line.

CONSTITUTIONAL EFFECTS OF OPERATIONS.

Every operation of any importance is followed by a certain degree of *shock* as indicated by a low temperature and a small and frequent pulse. As the shock passes off the temperature usually rises slightly above the normal point, the pulse becomes fuller and there is some thirst. This *traumatic fever*, if moderate and confined within certain limits, can scarcely be looked upon as a morbid condition; and unless it is kept up by some unhealthy state of the wound, by the presence of decomposing matter, or by pent-up discharges, it completely subsides by the third day. If the thermometer remain below 100° F. no anxiety need be felt on this score.

The **Local Treatment of Operation-Wounds** differs in no respect from that of accidental wounds, and will be treated of in the chapter on the treatment of such injuries.

The **Constitutional After-Treatment** of operations demands as much attention on the part of the Surgeon as the management of the wound itself. Immediately after the operation, and before the effects of the anæsthetic have passed off, the patient should be comfortably arranged in bed, with the clothes supported by a cradle, or other contrivance, away from the part implicated.

When the patient has fully recovered from the anæsthetic, if he is in much pain a hypodermic injection of morphia or a dose of laudanum may be given, but this should be avoided if possible, as it may cause vomiting. The patient should always be kept perfectly quiet.

The **Diet after the Operation** must depend upon the constitutional condition of the patient, his previous habits, his age, and upon the severity of the operation, and the septic or aseptic state of the wound.

As a general rule it is unwise to hurry the reaction after an operation by the administration of stimulants. A slow reaction gives more time for the perfect closure of the smaller vessels which have not been tied, and thus diminishes the chance of intermediate hæmorrhage. It is only in dangerously severe shock that stimulants are required. After minor operations the patient, if otherwise healthy, may be allowed his ordinary diet somewhat diminished in quantity and without stimulants. In more severe operations the Surgeon must be guided by the course taken by the wound and by the temperature. During the first two or three days there is usually some slight elevation of temperature, and the appetite is impaired by the anæsthetic and the sudden confinement to bed. During this period the patient will seldom care for solid food, and he should be restricted to farinaceous slops, beef-tea, soups, and light puddings, without stimulants. If the wound runs an aseptic course, the temperature will usually fall to normal by the third day; the appetite then returns, and the patient may be allowed to resume his ordinary diet.

limiting himself to plain dishes, and restricting the quantity while he is taking no exercise. Stimulants are not needed in such cases, but if the patient is in the habit of taking them with his meals he may be allowed to do so, the quantity being limited. No stimulants should be allowed between meals.

In cases in which the wound runs a septic course, with abundant suppuration and high fever, a very different diet may be necessary. Solid food cannot be taken under these circumstances, and if swallowed would not be digested. Strong beef-tea, thickened with the white of an egg or a small quantity of arrow-root, good soups, milk, milk and egg, milk and arrow-root, and other fluid foods can alone be taken, and in order to supply the necessary fresh vegetable element in the diet the patient may be allowed to quench his thirst with still lemonade. It is not my intention to enter upon the question of the use and abuse of alcohol as an article of diet; as a medicinal agent in severe surgical cases there can be no doubt of its utility. It can be used in three ways. In mild cases, without severe fever, it may promote the enjoyment of food and good digestion in those accustomed to its use. For this purpose good wine or well-brewed beer may be taken with meals, that stimulant being given to which the patient is accustomed in a state of health. In old and weakly people its administration in a dose sufficient to cause some increased force and frequency in the heart's action is most useful in preventing hypostatic congestion of the lungs and stagnation of blood in the extremities; conditions which not unfrequently play an important part in the causation of death. For this purpose a glass of one of the stronger wines or an ounce of good brandy or whisky may be given two or three times a day. Lastly, alcohol may be made to act as a food. It is not a true food, as there is no mechanism for storing it in the body, and if given in any but the smallest doses a large proportion comes off unaltered by the breath and in the urine, but if administered in very frequently repeated small doses it is completely consumed, coming off as carbonic acid and water, a process which is necessarily accompanied by a liberation of force in the body. It may often be given in this way at a time when the patient is incapable of taking or digesting any ordinary food, and is at the same time rapidly consuming his own tissues, as during severe septic fever. Given in this manner it diminishes tissue waste, and may maintain the patient's strength till the crisis of the fever is passed or the cause removed, or the effects of shock or loss of blood rallied from. By dilating the vessels of the skin it also aids in reducing the temperature. When stimulants are given with this intention, the dose should not exceed 1 drachm of proof spirit. It must be given at regular intervals, the frequency varying with the state of the patient. It may be necessary to administer it every ten minutes. The spirit must be of the best quality, and if really good brandy or whisky cannot be obtained rectified spirit diluted with water should be used. In less critical conditions the stimulant may be given with liquid food at frequent intervals. I have seen many patients saved by the free administration of brandy and wine with eggs and beef-tea from an early period after the operation.

In all this the Surgeon must be guided by the patient's pulse, tongue, and temperature, and nothing requires greater judgment than the administration of stimulants according to these particulars. Nothing can show greater want of judgment than indiscriminate "pouring in of brandy," often to the exclusion of food, under the idea that "alcohol gives strength."

It is of the utmost importance that the bowels should be kept regularly open, as constipation is often a great trouble from the sudden confinement to bed and loss of exercise. It is needless again to insist on the great importance of general cleanliness and ventilation.

The **remote effect** of the major operations is a subject that requires investigation. Do people who have undergone any of the greater operations, and who have recovered from the immediate effects, as a rule, live as long as those who have not sustained a mutilation? I am disposed to think that they do not. When we reflect on the number of persons who, before the age of thirty, suffer amputation of one of the limbs for injury, it is remarkable how seldom one sees an old person in a hospital or elsewhere, who has lost a limb in early life. I am, of course, speaking only of amputations for injury; for those who have undergone this operation for strumous affections or malignant tumours, frequently die early from recurrence of the disease in other parts of the body. So also with respect to lithotomy. Very many boys are cut for stone every year and recover; but I scarcely recollect to have met with a middle-aged adult who had been operated on in childhood.

The various Special Operations will be considered when treating of the several Injuries and Diseases for which they are required; but, as Amputations do not readily fall under any special head, being required for a great variety of different conditions, it will be more convenient to consider them here.

CHAPTER II.

AMPUTATIONS AND DISARTICULATIONS.

THE term *Amputation* means the separation of a part of the body. It is most commonly applied to the removal of a limb, but sometimes also to that of other parts, as the breast or penis.

The frequency of amputation of the limbs has much lessened of late years ; less severe modes of treatment being now followed in many cases of diseased joint and of compound fracture. Still amputations are among the most frequent operations in surgery, and will continue to be so as long as the human body is liable to severe mutilations, to gangrene of the limbs, and to incurable diseases of the bones and joints. It has been somewhat the fashion to decry amputation, and to speak of this operation as an opprobrium to surgery. "Any blockhead," says Kirkland, "can amputate a leg." Yet I cannot admit that the removal of a limb is an operation of less merit than any other, when adopted after all other means have failed, in curing the diseased part, or in saving the patient's life from danger. Surely, it is rather a subject of just pride than the reverse that the Surgeon is able to save the whole of the body by sacrificing a useless limb. It is true, of course, that no amputation should be undertaken except as a last resource and after due consideration; for, as John Woodall quaintly says, "it is no small presumption to dismember the image of God." In the performance of an amputation, also, much dexterity may be displayed; and there is great scope for skill in the constitutional treatment of the patient both before and after the operation.

Amputations may be required for *Injury* or for *Disease*. If performed for injury within the first few hours after the accident before traumatic or septic fever has set in, the amputation is termed *Primary*; if during the high febrile disturbance which accompanies septic inflammation and suppuration for the first eight or ten days, it is termed *Intermediate*; if after the subsidence of the fever, *Secondary*. Most commonly the term "intermediate" is not used, and all amputations for injury performed after the first twenty-four hours are classed as secondary.

The amputation of a limb is generally performed through the continuity of a bone; when done at a joint, it is called a *Disarticulation*.

History.—Amputation for diseases of joints and bones, or for the immediate effect of injury, is an operation of comparatively recent date; for the older Surgeons, with few exceptions, undertook the removal of a limb for gangrene only. So much was this the case, that in the works of many of the older writers the only mention of amputation is in the treatment of gangrene. In the works of Hippocrates (about 400 B.C.) in the book on Articulations, the following is the treatment recommended in gangrene:—"Those parts of the body which are below the boundaries of the blackening are to be removed at the joint, as soon as they are fairly dead and have lost their sensibility; care being taken not to wound any living part." Such a performance can

scarcely be called an amputation. Celsus, who lived at the commencement of the Christian era (B.C. 25 to A.D. 45) encouraged a bolder line of practice. The operation of amputation as described by him was thus performed: A deep incision was made to the bone between the living and the dead tissues, encroaching rather on the living than leaving any of the dead. When the bone was reached, the sound flesh was drawn back from it, and the saw applied as high as possible. The edges of the skin were then brought down, and it was recommended that the covering should be lax, that it might as nearly as possible cover the bone. As, however, Celsus advises that the part which the skin did not reach should be dressed with lint and a sponge squeezed out of vinegar, it is probable that in many cases at least the covering was not sufficient to make a perfect stump. Celsus was acquainted with the use of the ligature, and it is possible, therefore, that the vessels were secured by that means, but no distinct mention of it is made in his description of the operation. Whatever the method may have been that he adopted for arresting hæmorrhage, it seems not to have been very efficient, for he tells us that the operation was attended by very great danger, the patients often dying during its performance, either from hæmorrhage or fainting. "But," he says, "in this it is not to be considered, whether the remedy is very safe, for it is the only one we have." Towards the end of the first century Archigenes (A.D. 48—117), a Greek practising in Rome, whose writings are quoted by Oribasius, extended the field of the operation, recommending it in cases of severe wounds, cancer and incurable ulcers. He attempted to arrest bleeding during the operation by the use of the "fillet," a band bound tightly round the limb. He also recommended tying the large vessels before dividing them, but the exact method in which he did it is not clear. Heliodorus, who flourished about the same time, performed the operation in two stages, dividing first those parts that contain no large vessels, then sawing the bone, and finally cutting through the remaining tissues, with the large vessels to which he applied the actual cautery. Galen (A.D. 131—201), who also practised in Rome, describes the operation only as performed for gangrene. He relapsed somewhat towards the practice of Hippocrates, for although cutting in the line of demarcation between the dead and the living tissues, he recommended the operator to encroach rather on the former than the latter and afterwards to apply a cautery to such dead tissue as was left behind. From this time to the thirteenth century no important change took place in the method of operating, Galen's practice being generally adopted. During the whole of this period amputation seems to have been practised chiefly, if not solely, for gangrene, and although the use of the ligature was frequently recommended for accidental wounds of arteries, the cautery was exclusively used in amputations. In the thirteenth century Theodoricus (1205—1298) repeated the instructions given by Celsus, but the operation seems not to have found much favour, for in the following century Guy of Chauliac, although he described the operation by the knife, expressed his preference for a method of his own invention, which consisted in strangulating the limb by plasters applied tightly above a joint and allowing it to drop off. His reason for this was that if the limb were amputated in the ordinary way the patient might bear malice against his Surgeon, believing that it might have been saved. It was not till 1520 that the method of Celsus was definitely revived as the rule of practice by

Hans von Gersdorff, but as the cautery, or some more or less impotent styptic, was still the means employed to stop the bleeding, but little real progress was made. In the middle of the sixteenth century, about 1552, Ambrose Pare, the most celebrated Surgeon of his time, extended the use of the ligature to vessels wounded in amputations, arguing that, if the ligature were useful in accidental wounds and in varices, it was equally applicable to vessels divided in amputations. Amputation, as performed by Pare, was essentially the same operation as that described by Celsus, and although the arrest of bleeding was efficiently carried out by the ligature, the loss of blood during the operation was often considerable; for, though the "fillet" was bound tightly round the limb with the intention of diminishing the hæmorrhage, it seems never to have been applied with sufficient force completely to arrest the circulation. The instruments used for seizing the vessels were somewhat clumsy, and consequently the patient often lost so much blood before the ligatures were applied, that the majority of Surgeons continued for another century to prefer the cautery or some styptic. It was not until the beginning of the eighteenth century that the ligature really became the only recognised mode of arresting arterial bleeding. This result was brought about partly by the discovery of the circulation of the blood by Harvey in 1628, but chiefly by the invention of a really efficient tourniquet by Morel in 1674. Surgeons now were able to perform amputations without the fear of seeing their patient die of hæmorrhage during the operation, and from that time real improvement commenced.

In 1679, Lowdham, an English Surgeon, first suggested the plan of cutting a flap which could be made to cover the divided end of the bone, so as to obtain early union without necrosis and separation of the end of the bone. Thus there came to be two distinct modes of amputating a limb, the circular and the flap method, each of which underwent gradual development and improvement.

Amputation by the Circular Method.—The first improvement of the circular method of amputating, made after the invention of the tourniquet, was the introduction of what was known as the operation "*by the double incision.*" This mode of operating was introduced into practice almost simultaneously by Cheselden (1688—1751) of London, and J. L. Petit (1674—1750), of Paris. In this mode of operating, the skin and fat were divided by a circular incision; the assistant then, grasping the limb, pulled the integuments forcibly upwards, and the muscles were cut through to the bone by another circular sweep of the knife. The periosteum was then scraped from the bone with the back of the amputating knife for some distance upwards and the saw applied as high as possible. In the leg and forearm a smaller straight knife was used for cleaning the bones. This method did not aim at completely covering the bone, but it provided such an amount of covering that it was possible for the stump to heal completely by granulation, usually after separation of the protruding end of the bone. The results were not so bad as might have been expected. The first Monro, who wrote in 1736, tells us that out of ninety-nine major amputations performed by himself and his colleagues in the Edinburgh Infirmary, only eight died, and none of these from the immediate effects of the operation. Monro secured the vessels by ligature, and dressed the raw surface of the stump with dry lint, which remained on till it was loosened by suppuration. A modification of the operation by the double

incision was introduced by the French Surgeon, Louis, in 1768. He noticed that, in making the circular incision through the muscles, the retraction of the superficial layers was greater than that of those near the bone. In order, therefore, to obtain a higher and more level division of the muscles, he divided the superficial layers with the skin and fat, and having drawn them forcibly upwards, cut the remaining muscle with a second sweep of the knife. A linen retractor was applied between the first and second incisions, and in order to allow the muscles to retract to the fullest possible extent, Louis was inclined to abandon the tourniquet and to trust to digital compression of the main arterial trunk. So far Surgeons had advanced little beyond the operation of Celsus; in fact, it is doubtful whether in amputation by the double incision, as performed at this time, the bone was better covered than in that by the Roman Surgeons, who raised the soft parts very freely before sawing. The first

Fig. 21.- Amputation of Arm by the Circular Method. Commencement of first incision.

attempt to diminish the size of the raw surface left after amputation was made by Samuel Sharp about 1750. He passed two broad ribbon-like ligatures, each composed of eight well-waxed threads, through the edges of the wound about three-quarters of an inch from the margin of the skin, and drawing them tolerably tight, tied them in a bow-knot. It was soon found, however, that the tension thus caused produced such an amount of pain and fever that the plan was abandoned almost as soon as it was recommended.

Between 1770 and 1780 the great fact became recognised that the only way to obtain speedy healing of a stump is to provide sufficient covering to enable the edges of the skin to be brought together over the end of the bone, so as to meet easily without tension. This led to the invention of the mode of operating known as *amputation by the triple incision*, which was introduced into practice almost simultaneously by Benjamin Bell, of Edinburgh, William

Hey, of Leeds, and Alanson, of Liverpool. The two former performed the operation exactly as it is done in the present day by those who practise that method (Figs. 21 and 22). The skin and fat were first divided by a single sweep of the knife and dissected up for a distance equal to half the diameter of the limb; the muscles were then divided by another circular sweep of the knife and retracted for a distance varying from one to two inches, according to the thickness of the limb; and the bone was sawn as high up as possible. In the thigh and leg it was recommended by Hey to cut the posterior muscles longer than the anterior, to allow for their greater retraction. The edges of

Fig. 22. Amputation of the Arm by the Circular Method. Sawing the Bone.

the skin were brought together in the transverse diameter of the limb, and a stump was formed with abundant covering for the bones, but necessarily with some puckering and projection at each angle.

The three incisions which gained for this operation the name of "the triple incision" were, first, the incision through the skin and fat; secondly, the incision through the muscles; and finally, the circular sweep round the bone to separate the muscles for retraction. The method adopted by Alanson produced much the same result, the only difference being that he attempted to divide the muscles in such a way as to leave a hollow cone with the bone at its apex, by turning the edge of the knife obliquely upwards. This proceeding was found by other Surgeons to be inconvenient, although in Alanson's hands it produced excellent results.

Amputation by the Flap Method was invented in this country by Lownham, and was first described in a work by J. Yonge, with the extraordinary title of "*Curus Triumphalis e Terebintho*," published in 1679.

The operation was at first performed only in the leg, and the flap which was made from the calf was cut by dissection, and was composed chiefly of the integuments and subcutaneous tissues. In 1696, Verduin, of Amsterdam, independently invented a similar operation, but his method differed from that of Lowdham in the flap being cut by transfixion, instead of being raised by dissection. Both Lowdham and Verduin hoped to be able to arrest hæmorrhage by pressing the flap against the ends of the bones and securing it by bandages. The result was, that although in a few cases, especially in the hands of Yonge, who understood the necessity of drainage, union by first intention seems to have taken place, in the great majority the discharges were pent up and set up violent inflammation. In consequence of the unsatisfactory nature of the results obtained, the method was completely abandoned till 1739, when it was reintroduced by a French Surgeon named Ravaton, who modified the operation by making two rectangular flaps, one from each side of the limb, and securing the vessels by means of the ligature. A similar operation was performed by Vermale, of Mannheim, in 1767, in the lower part of the thigh. That the flap method still did not yield very favourable results, on account of the tendency to accumulation of discharges between the flaps in the absence of any proper system of drainage, is evident from the fact that in 1765, O'Halloran, "surgeon and man-midwife" at Limerick, who amputated by a single long flap, recommended that the flap and stump should be dressed as separate sores, and that they should not be brought together till the surfaces were covered by granulations. This plan did not, however, find much favour, and at the end of the last century Surgeons preferred the circular amputation in most cases, the flap operation being limited almost entirely to the upper part of the leg, the lower part of the thigh, and the distal parts of the foot. Almonson and Hey, whose names have already been mentioned in connection with the circular method of amputation, practised and improved the flap operation in those situations. During the first fifty years of this century, however, the flap operation came greatly into favour in this country, and was during the latter part of that time supported by the able advocacy of Liston, who invariably amputated by that method, and who certainly did it with wonderful rapidity and precision.

Amputation by the double flap, as it is still practised, is thus performed (Fig. 23). The two flaps may be made either by dissection, cutting from without inwards; or by transfixion, cutting from within outwards. Transfixion is adapted only to fleshy parts, as the thigh or arm; but cutting from without inwards will be found to afford the best result, and is indeed the only mode of forming the flap in some situations in which the bones are naturally thinly covered, as on the dorsal aspect of the fore-arm, the anterior part of the leg, or just above the ankle-joint, or where the soft parts have been wasted by chronic disease. The flaps in transfixion should be made by a steady sweeping cut, so that the soft parts may be evenly and smoothly divided. Their length must, of course, be proportioned to the thickness of the limb. If they be cut too long, too much muscle will be left on the stump, and the flap itself is usually badly fashioned and pointed. Should the Surgeon feel that he has made this mistake, the wiser plan will be at once to round off the ends of the flaps. Should they have been cut too short, the soft parts must be forcibly retracted, and the bone cleared by circular sweeps of the knife, and sawn as high up as possible.

The flap farthest from the great vessels, as that on the outer side of the thigh or arm, should be cut first. In making the inner flap, great care must be taken to wind the point of the knife well round the bone, so as not to transfix and split the vessels, but to cut them as long as possible. As a general rule, the less loose muscle that is left on the stump, the better; hence, where there is an

Fig. 25. Amputation of the Thigh. Antero-posterior Flap Operation. Flaps cut by Transfixion.

equal thickness of soft parts round the bone, as in the arm and thigh, the flaps should be cut short, well retracted, and the bone cleared by circular sweeps of the knife as high as necessary. The bone thus lies at the bottom of a deep hollow beyond the angle of junction of the flaps, and there is less chance of a conical stump being left.

In cutting a flap from without inwards, it is of the greatest importance to remember that the edge of the knife must never be turned towards the under surface of the flap, but always towards the parts to be removed. After marking out the flap with the point of the knife, the Surgeon takes the edge of the skin between the finger and thumb of his left hand and raises it from the parts beneath. The portion of the flap which is thus raised is therefore at right angles to the surface of the limb, and the knife must also be kept in a similar direction, or its edge will be turned towards the base of the flap, and by severing its under surface will greatly increase the danger of sloughing. The flap must be raised evenly across the limb, and one side must not be allowed to get in advance of the other. When bands of areolar tissue are seen passing from the flap to the parts beneath, the operator must divide these at the end that is attached to the parts to be removed. There should be no hurry about raising the flap by dissection, as under the influence of anesthetics

the lengthening of the operation by two or three minutes is a matter of but little importance. It is better to spend one or two minutes more over the operation, than to have to re-amputate on account of sloughing of the flaps.

The simple circular and the double-flap operations being thus brought to perfection marks the limit of the improvement in amputation which resulted from the invention of the tourniquet ; and before the invention of anæsthetics Surgeons were divided in opinion as to which of the two methods was to be preferred when the nature of the case allowed of a choice. The advocates of the flap operation claimed for it the following advantages : that it was easy of performance, and could be carried out with great rapidity, thus saving pain to the patient ; that the thick muscular cushion left over the end of the bone made a better covering and rendered protrusion of the bone less likely to occur ; and that the accuracy of fit obtained by this method favoured union of the wound by first intention. The advocates of the circular method maintained that the light covering formed by the skin and fat was less likely to be displaced by the involuntary movements of the muscles, and was quite as capable of uniting by first intention as fleshy flaps ; and that protrusion of the bone was not dependent on the method adopted, but upon insufficiency of covering. As long ago as 1783 it had been pointed out by Mynors that the muscular cushion is more an ideal than a real advantage ; for in course of time the muscular tissue in the flap becomes atrophied and absorbed, until after a few months the difference in covering between a stump formed by the flap method and one by the circular is inappreciable. The advocates of the circular method also maintained that the vessels being cut transversely retract more perfectly, and are less likely to bleed afterwards, and that the wound resulting from the operation is smaller than that produced by the flap method. The great objection to the circular operation was undoubtedly its tediousness and painfulness, and consequently the flap operation became decidedly the favourite with most Surgeons. The invention of anæsthetics, however, left the Surgeon free to consider solely what method of amputation furnishes the best results. Hence many plans of operation that were almost discarded thirty years ago have regained their ascendancy, and flaps are now most frequently carved out by cutting from without inwards, regardless of the greater length of time required, provided the result is more satisfactory.

As a result of the thought and labour devoted to the improvement of amputation since the invention of anæsthetics, certain general principles have come to be universally recognised as guiding the Surgeon in the performance of the operation. These may be briefly stated thus :—

1. The covering must be sufficient to meet over the bone without the slightest tension ;
2. The amputation should be so performed that the scar, when the stump is healed, shall not lie over the end of the bone ;
3. If possible, a dependent opening should be provided for the exit of the discharges ;
4. These advantages must be obtained with the smallest possible sacrifice of the healthy parts of the limb.

Each of these requires consideration more in detail.

1. TO PROVIDE A SUFFICIENT COVERING.—It was long ago pointed out by Mynors that the standard by which we must estimate the amount of covering required is the diameter of the limb at right angles to the line in which the

circumference is to be placed, and taken at the point at which the bone is to be divided. In operating on the dead body, it is evident that if two equal flaps, each half the diameter of the limb, were cut, measuring from the point at which the bone is sawn to the end of the flaps, they would accurately meet and cover in the bone, but such flaps in the living body would be totally inadequate on account of the shrinking from the elasticity of the skin and the displacement from the contraction of the muscles. Consequently, it is necessary to provide another half diameter of covering *at least*, and in some situations even this amount is insufficient. As an illustration of the above rule, let us suppose a limb is to be amputated, the antero-posterior diameter of which, at the point where the bone is to be sawn, is six inches, the necessary diameter and a half of covering could be obtained in the following ways amongst others:—1. One long flap nine inches long; 2, two flaps, one six inches long and the other three; 3, two equal flaps four and a half inches long; 4, two equal flaps three inches long, and retraction of the muscles from the bone to such an extent as to provide an inch and a half of covering on each side; 5, a circular incision raising the skin and fat for three inches, and another circular cut through the muscles with retraction of the soft parts from the bone for one inch and a half.

The general rule that one diameter and a half is sufficient, requires modification under various conditions of the tissues of which the covering is made, and in various situations. In very old people the skin has frequently lost much of its elasticity, but it is not wise to shorten the covering on this account, as the tissues being feeble are less capable of withstanding the irritating effect of tension. In amputation through chronically inflamed tissues, the retraction is also reduced to a minimum on account of the rigidity of the parts; but here again it is unwise to shorten the covering; in fact it is better to make it a little longer, as the flaps are very apt gradually to shrink during or after the healing of the stump. In limbs in which the muscles have undergone extreme fatty degeneration, the retraction caused by their tonic contraction is absent, so that the minimum covering of a diameter and a half is amply sufficient. In the lower third of the thigh the covering should always be increased to two diameters to allow for the very excessive retraction of the long flexor muscles of the leg. In amputation of the leg by the long calf-flap, it is also necessary to provide very abundant covering to allow for the subsequent shrinking of the muscular tissue which forms the posterior flap.

2. THAT THE SCAR SHALL NOT BE OVER THE END OF THE BONE.—It is evident in the first place that protrusion of the bone is more likely to occur if the two flaps in a flap amputation meet exactly over its end; but the chief object in placing the scar so that it shall be free from the bone is to avoid a painful stump. If the scar in the skin is adherent to the bone it becomes extremely liable to ulceration from slight injuries. If the scar be placed well away from the bone, it is often possible in amputations of the lower limb for the patient to bear a certain proportion of his weight on the end of the stump, which gives greatly increased steadiness in walking on an artificial limb.

3. THAT A DEPENDENT OPENING IS TO BE PROVIDED FOR THE EXIT OF DISCHARGE. This may be stated in other words thus: that the covering of the stump shall be taken chiefly from the dorsal surface of the forearm, and from the anterior part of the limb elsewhere. Perfect drainage is essential for union of any wound by first intention, and consequently it is needless to

the lengthening of the operation by two or three minutes is a matter of but little importance. It is better to spend one or two minutes more over the operation, than to have to re-amputate on account of sloughing of the flaps.

The simple circular and the double-flap operations being thus brought to perfection marks the limit of the improvement in amputation which resulted from the invention of the tourniquet ; and before the invention of anæsthetics Surgeons were divided in opinion as to which of the two methods was to be preferred when the nature of the case allowed of a choice. The advocates of the flap operation claimed for it the following advantages : that it was easy of performance, and could be carried out with great rapidity, thus saving pain to the patient ; that the thick muscular cushion left over the end of the bone made a better covering and rendered protrusion of the bone less likely to occur ; and that the accuracy of fit obtained by this method favoured union of the wound by first intention. The advocates of the circular method maintained that the light covering formed by the skin and fat was less likely to be displaced by the involuntary movements of the muscles, and was quite as capable of uniting by first intention as fleshy flaps ; and that protrusion of the bone was not dependent on the method adopted, but upon insufficiency of covering. As long ago as 1783 it had been pointed out by Mynors that the muscular cushion is more an ideal than a real advantage ; for in course of time the muscular tissue in the flap becomes atrophied and absorbed, until after a few months the difference in covering between a stump formed by the flap method and one by the circular is inappreciable. The advocates of the circular method also maintained that the vessels being cut transversely retract more perfectly, and are less likely to bleed afterwards, and that the wound resulting from the operation is smaller than that produced by the flap method. The great objection to the circular operation was undoubtedly its tediousness and painfulness, and consequently the flap operation became decidedly the favourite with most Surgeons. The invention of anæsthetics, however, left the Surgeon free to consider solely what method of amputation furnishes the best results. Hence many plans of operation that were almost discarded thirty years ago have regained their ascendancy, and flaps are now most frequently carved out by cutting from without inwards, regardless of the greater length of time required, provided the result is more satisfactory.

As a result of the thought and labour devoted to the improvement of amputation since the invention of anæsthetics, certain general principles have come to be universally recognised as guiding the Surgeon in the performance of the operation. These may be briefly stated thus :—

1. The covering must be sufficient to meet over the bone without the slightest tension ;
2. The amputation should be so performed that the scar, when the stump is healed, shall not lie over the end of the bone ;
3. If possible, a dependent opening should be provided for the exit of the discharges ;
4. These advantages must be obtained with the smallest possible sacrifice of the healthy parts of the limb.

Each of these requires consideration more in detail.

1. TO PROVIDE A SUFFICIENT COVERING.—It was long ago pointed out by Mynors that the standard by which we must estimate the amount of covering required is the diameter of the limb at right angles to the line in which the

cicatrix is to be placed, and taken at the point at which the bone is to be divided. In operating on the dead body, it is evident that if two equal flaps, each half the diameter of the limb, were cut, measuring from the point at which the bone is sawn to the end of the flaps, they would accurately meet and cover in the bone, but such flaps in the living body would be totally inadequate on account of the shrinking from the elasticity of the skin and the displacement from the contraction of the muscles. Consequently, it is necessary to provide another half diameter of covering *at least*, and in some situations even this amount is insufficient. As an illustration of the above rule, let us suppose a limb is to be amputated, the antero-posterior diameter of which, at the point where the bone is to be sawn, is six inches, the necessary diameter and a half of covering could be obtained in the following ways amongst others:—1. One long flap nine inches long; 2, two flaps, one six inches long and the other three; 3, two equal flaps four and a half inches long; 4, two equal flaps three inches long, and retraction of the muscles from the bone to such an extent as to provide an inch and a half of covering on each side; 5, a circular incision raising the skin and fat for three inches, and another circular cut through the muscles with retraction of the soft parts from the bone for one inch and a half.

The general rule that one diameter and a half is sufficient, requires modification under various conditions of the tissues of which the covering is made, and in various situations. In very old people the skin has frequently lost much of its elasticity, but it is not wise to shorten the covering on this account, as the tissues being feeble are less capable of withstanding the irritating effect of tension. In amputation through chronically inflamed tissues, the retraction is also reduced to a minimum on account of the rigidity of the parts; but here again it is unwise to shorten the covering; in fact it is better to make it a little longer, as the flaps are very apt gradually to shrink during or after the healing of the stump. In limbs in which the muscles have undergone extreme fatty degeneration, the retraction caused by their tonic contraction is absent, so that the minimum covering of a diameter and a half is amply sufficient. In the lower third of the thigh the covering should always be increased to two diameters to allow for the very excessive retraction of the long flexor muscles of the leg. In amputation of the leg by the long calf-flap, it is also necessary to provide very abundant covering to allow for the subsequent shrinking of the muscular tissue which forms the posterior flap.

2. THAT THE SCAR SHALL NOT BE OVER THE END OF THE BONE.—It is evident in the first place that protrusion of the bone is more likely to occur if the two flaps in a flap amputation meet exactly over its end: but the chief object in placing the scar so that it shall be free from the bone is to avoid a painful stump. If the scar in the skin is adherent to the bone it becomes extremely liable to ulceration from slight injuries. If the scar be placed well away from the bone, it is often possible in amputations of the lower limb for the patient to bear a certain proportion of his weight on the end of the stump, which gives greatly increased steadiness in walking on an artificial limb.

3. THAT A DEPENDENT OPENING IS TO BE PROVIDED FOR THE EXIT OF DISCHARGE. This may be stated in other words thus: that the covering of the stump shall be taken chiefly from the dorsal surface of the forearm, and from the anterior part of the limb elsewhere. Perfect drainage is essential for union of any wound by first intention, and consequently it is needless to

point out the importance of so arranging the covering that the force of gravity shall aid, and not oppose, the escape of discharges. In exceptional cases, as in some of the amputations in the foot, the advantages of the flap taken from the heel or sole in providing a covering upon which the patient can bear his whole weight are sufficient to counterbalance the difficulty of drainage that sometimes is met with in these operations. If the covering be taken chiefly from the front of the limb, it is evident that not only will gravity aid in draining the wound, but also that it will tend to keep the longer flap in its position. If the covering be taken chiefly from behind, as in the transfixion-amputation in the leg, the tendency of the heavy muscular flap to fall backwards can be counteracted only by fixing it to the anterior by sutures or strapping; tension of the short flap is produced and it may slough over the bone; any insufficiency in external support allows the posterior flap to fall away, fluids bag in the gap, and speedy union is impossible.

4. THAT THESE ADVANTAGES ARE TO BE GAINED WITH THE SMALLEST POSSIBLE SACRIFICE OF THE LENGTH OF THE LIMB.—Experience has shown conclusively that the danger of an amputation increases as the point at which the bone is sawn approaches the trunk. It is evident that the bone can be sawn at the lowest possible point if the covering is taken equally from the two sides. To take as an example a limb the antero-posterior diameter of which is six inches, and which consequently requires nine inches at least of covering to form a good stump, and supposing the nature of the case makes it impossible to obtain covering from a point lower than the end of the bone to be sawn through, if it is to be taken equally from the two sides, the bone would be sawn four-and-a-half inches above its lower end; if from one side only, nine inches. If, however, the anterior flap was five-and-a-half inches long and the posterior three-and-a-half, the advantages of a dependent opening and a scar removed from pressure could be obtained with the sacrifice of only one inch more bone than if the flaps had been of equal length. The Surgeon will therefore adhere to the rule of taking the covering as equally as possible from the two sides of the limb only as far as is consistent with the other essentials of a good amputation, a dependent opening for drainage, and a scar away from the bone. A longer stump is more easily fitted with an artificial limb and gives the patient greater control over it.

These essential features of a good amputation being agreed upon, the questions of the best material of which to form the covering, and the best way of raising it, remain to be considered.

All Surgeons are now agreed that too much muscle in a flap is an unmitigated evil. The objections to muscular flaps are, that they are heavy, and consequently liable to be easily displaced; that, supposing any voluntary movement or involuntary jerking or twitching of the limb to occur, the surfaces of the flaps are moved upon each other, and primary union is thus prevented, and that this is especially likely to happen if the sharp edge of the sawn bone is in direct contact with a muscular flap bent over its end; that muscular flaps retract to a considerable extent after the operation, and continue to shrink for some time, thus causing a greater tendency to protrusion of the bone; and lastly, that as in the end the muscle completely wastes away, the idea that a muscular flap forms a better cushion than one composed only of the skin and subcutaneous fat is erroneous. None of these objections can be raised to a covering composed solely of the cutaneous and subcutaneous tissues, but, on

the other hand, in very emaciated subjects, such a covering is very thin, and is apt to suffer from the direct pressure of the bone against it, and consequently in such cases it is well to protect it by raising a certain amount of muscle with it. Skin flaps also, if very long, are apt to slough, as their vascular supply is somewhat limited, and this accident is especially liable to happen in old people. In any patient, whether young or old, fat or thin, sloughing will almost certainly occur if the Surgeon turns the edge of the knife towards the flap instead of keeping it directed to the parts to be removed. Common sense would suggest also that it is wise to thicken the base of a flap with a little muscle when possible, if circumstances require it to be made of more than ordinary length. If the covering in most parts were made solely of skin and fat, the retraction of the muscles would leave the bone protruding sharply beneath the flaps, and the object of the Surgeon is therefore to save so much muscle that after full retraction has taken place it shall still be level with the seen end of the bone. In order to obtain this result, the proportions usually sufficient are to provide one diameter of covering composed of the skin and subcutaneous structures, and half a diameter of muscle, or more if the retraction is expected to be considerable, as in the lower part of the thigh. In all cases the operator should bear the principles in mind, and be guided in his performance by circumstances, considering the age and state of health of the patient, the amount of subcutaneous fat, the length of the flaps, and the situation of the amputation, and suiting the relative proportions of skin and muscular covering to the nature of the case. A mere mechanical amputator can never be a good one.

In amputating for diseased joints, it often becomes a question whether the structures covering the articulation are in a fit state to be used in the formation of flaps. As a general rule, it may be stated that the chronically inflamed tissues covering a diseased joint, even when perforated here and there by sinusses, form excellent flaps: but it must be borne in mind that their vitality being somewhat lower than natural, they must be carefully handled to avoid unnecessary bruising, and that they are liable to shrink considerably as the stump heals, and consequently their length must be slightly greater than if the tissues were healthy. In tuberculous disease of joints any pulpy granulation tissue which may be left in the flap should be carefully dissected away, and sinusses scraped with a sharp spoon, and disinfected with some powerful antiseptic. Such flaps yield a large amount of serous exudation during the first few hours after the operation, and ample drainage must be provided for this.

In some of the modern methods of amputating about to be described it has been the object of the Surgeon to combine as far as possible the advantages of the circular and flap methods in one—following the rules just laid down as to the essentials of a good amputation.

Amputation by the Modified Circular Method.—In 1839, Liston proposed a combination of the double flap and circular operations, which greatly improved the shape of the stump of the circular method, and somewhat increased the ease of the operation (Fig. 24). Two semilunar incisions, with their convexities downwards, are made through the skin from side to side of the limb; the flaps, which are each about one quarter of the diameter of the limb in length, are then dissected up and the skin and fat raised circularly above the angle of union for a distance equal to the length of the flaps, thus exposing the muscles half a diameter above the extremities of the flaps. The

operation is then completed by division and retraction of the muscles as in the ordinary circular method. This operation is especially indicated in muscular parts, such as the arm, thigh, or leg. The advantage of this procedure over the ordinary flap-operation is very great in stout muscular subjects.

Fig. 24.—Modified Circular Amputation in the upper third of the Leg.

Amputation by a long and a short rectangular flap. Teale's Method.—The late Mr. Teale of Leeds, in 1853, invented a method of amputating by a long and a short rectangular flap. In selecting the structures for the formation of the long flap "such parts must be taken as do not contain the larger bloodvessels and nerves." In the lower part of the thigh and in the leg the long flap will therefore be anterior and the short posterior: in the fore-arm the long is dorsal and the short palmar, and in the arm the long flap will be chiefly taken from the outer side.

The long flap is a perfect square, and the rule for its formation is, that its length and breadth must each be equal to half the circumference of the limb at the place of amputation (Fig. 25). If the circumference be 12 inches, the length and breadth of the flap, both at its base and at its free extremity, should be 6. The short flap is to be one-quarter the length of the anterior flap; in the case above supposed it would be $1\frac{1}{2}$ inches. In performing the operation the measurements must be carefully made, and the outline of the flaps marked on the limb with ink. Both flaps are to be made to include all the soft parts of the limb. The bones are sawn in the angle of union of the flaps, without any previous retraction of the soft parts. After the vessels have been secured, the long flap is folded over the end of the bone, and attached by suture, partly to the short flap, and partly to itself; thus the proximal quarter of the long flap is first accurately sewn to the short flap: the remaining part of the long flap is then doubled over on itself, its free end being accurately fitted to the free end of the short flap, and attached by sutures; finally stitches are applied where the terminal part of the flap is in contact with the second quarter, as in the figure (Fig. 26). The advantages claimed by Teale for his method of amputating were, that it provides an abundant covering free from tension. This it evidently does, as the covering amounts to $1\frac{1}{4}$ diameters of the limb. Secondly, it provides a dependent opening for the exit of discharge; and thirdly, that when it is healed the cicatrix is behind the bones, and that consequently the patient can bear the whole or a part of his weight on the end of the stump; this is especially advantageous after amputation in the thigh or leg, where a stump capable of bearing direct pressure would be of very

essential service to the patient. Teale advised, however, that the whole pressure be not borne on the end of the bone, but that it be reduced to one-half by an elastic pad composed of numerous layers of flannel beneath the end of the stump, the remainder of the weight being distributed in the usual way on the upper part of the limb: thus not only relieving the stump, but securing greater steadiness of gait. In the upper extremity, however, no direct pressure is made upon the end of the stump in the adaptation of artificial limbs: hence, the rectangular appears in these situations to possess no advantage over the other double-flap methods, so far as the utility of the stump is concerned.

But, whilst fully admitting the advantage possessed by the rectangular method in the formation of a well-covered stump, especially in the lower extremity, we must not close our eyes to certain disadvantages which appear to me to be inseparable from it. One disadvantage consists in the necessity of sawing the bone at a higher point when one flap is made of such extreme

Fig. 20. Lines of Incision in Teale's Amputation.

Fig. 21. Teale's Amputation: Stump.

length than when two shorter ones more nearly equal are fashioned. Thus, for instance, in an amputation of the thigh for injury about the knee-joint, the long rectangular flap in an adult would require to be about 8 inches in length, and the femur must consequently be sawn at least as far as this above the patella: whereas, in the ordinary double-flap amputation, two shorter flaps, each about 4 inches in length, will be found sufficient to cover in the bone, which may consequently be sawn at a proportionately lower point. Thus the rectangular method contravenes the principle in amputation, not to remove the limb at a higher point than is absolutely necessary, the danger to life increasing with every inch that is removed. In amputations for malignant disease, also, the long flap, which has to be cut close to the morbid growth, would run a greater risk of infiltration than two shorter ones taken higher up in the limb: the bone in both cases being sawn at the same level.

Should union by the first intention fail and suppuration ensue, in the rectangular amputation the thick fleshy mass which enters into the formation of the long flap becomes a source of great inconvenience, bulging out from under the skin, and requiring considerable management in the after-treatment.

For these reasons the unmodified form of Teale's amputation is hardly to be recommended.

Amputation by the long Anterior Flap.—At the time that Teale was recommending the long rectangular flap in all parts of the body, Carden, of Worcester, was advocating the employment of a long anterior flap in a form of amputation invented by him for removal of the thigh immediately above the knee. In his operation, which will be described amongst the special amputations, a single long anterior flap was made, the extremity of which was rounded in form.

Spence of Edinburgh, who fully recognised the advantages of Teale's

method of amputation in the lower third of the thigh, suggested a modification by which he hoped to obtain them with less trouble and without producing so large a wound. He made no posterior flap, but compensated for it by retracting the soft parts from the bones to an extent equal to its length. The anterior flap was to be made a little longer than the diameter of the limb; and its angles being rounded, it was allowed simply to hang over the end of the stump, without being folded upon itself as in Teale's operation. The posterior parts were divided from without inwards by a single sweep of the knife. By this method, however, the bone was sawn as high as in Teale's method, so that the gain was not very great.

In 1860 Lister pointed out that the advantages of Teale's method could be obtained with considerably less sacrifice of length in the limb by taking the covering more equally from the anterior and posterior aspects. A dependent opening for the exit of the discharges, and a scar placed behind the bones may be obtained in almost all situations by making an anterior flap two-thirds of the diameter of the limb in length, and a posterior half that length, as the bone is in almost all parts situated more towards the anterior than the posterior aspect of the limb. In all parts of the limbs the flexors, being the muscles with the longer bellies, retract more extensively than the extensors; and, consequently, if, when the operation is finished, the line of union of the flaps is on the flexor aspect of the bones, it is quite certain that the scar, when the stump is healed, will be in a similar position. The method of operating, therefore, recommended by Lister as best suited to the amputations of the forearm, leg, and thigh, is the following. An anterior rounded flap, equal in length to two-thirds of the antero-posterior diameter of the limb at the point at which the bone is to be sawn, is raised by dissection. In the lower thirds of the leg and forearm the bones form so large a proportion of the limb that, in order to make sure that the scar shall be placed behind them, it is necessary to make the length of the anterior flap equal to the diameter of the limb. In raising the anterior flap the operator will, if he think fit, try to take up some muscle at its base to thicken it and so ensure its vitality. This is to be recommended for all parts in thin or feeble subjects, and in the thigh in every patient. The flap is not, however, under any circumstances to be too fleshy and heavy. A posterior skin-flap, half the length of the anterior, is next raised. The muscles are then divided circularly and retracted from the bone for a distance equal to at least one quarter of the diameter of the limb; in the thigh it is better always to retract for half a diameter. It is evident that in the leg this retraction may be rather difficult, especially in secondary amputations in which the tissues are swollen and infiltrated; but the difficulty is easily overcome by extending the incision upwards from the angle of the flaps, either on one or both sides of the limb, to the point at which the bones are to be sawn. This mode of amputating combines the advantages of both the circular and the flap operations: it has the light covering and absence of excessive muscle of the circular, with the accurate fit, the good drainage, and the well-placed scar of the flap method. It is in fact a combination of the flap and circular operations, and therefore sometimes is spoken of as the "combination method."

Amputation by the Oval Method, which is especially adapted to removal of fingers or toes and disarticulations at the shoulder and hip, is essentially a circular amputation with a longitudinal incision made up one side of the limb,

to facilitate the retraction of the soft parts and the exposure of the joint at which disarticulation is to be performed. The oval form is given by rounding off the angles formed by the junction of the longitudinal with the circular incision. When the longitudinal incision is continued for some distance above the commencement of the true oval part, the operation is frequently spoken of as amputation by the "racket-shaped incision."

Sawing the Bone.—In all methods of amputating, as soon as the incisions have been made through the soft parts, the bones must be cleared for the application of the saw. While doing this the soft parts must be firmly retracted by the assistant or by the Surgeon himself, if he stands so as to take his own flaps. For the purpose of retraction the hands are usually sufficient, though some Surgeons still use retractors made of pieces of stout calico or linen. The retractor must be about 2 inches wider than the diameter of the limb and about 3 feet long. If there is only one bone, one end must be torn into two tails. The retractor is soaked in an antiseptic lotion, and the two tails of the divided end are then passed one on each side of the bone and slightly crossed on each other. The assistant then, taking the two tails in one hand and the undivided end in the other, pulls them forcibly upwards. If there are two bones, the divided end must be torn into three tails, the middle one of which is passed between the bones. Retractors are of use only in circular or combined flap and circular amputations. In the pure flap operations they are unnecessary for retraction of the soft parts, but they are still of use in protecting the muscles from the teeth of the saw and in keeping the surfaces free from the bone-dust: for the laceration of the deep muscles by the saw and the imbedding of bone-dust in their substance may interfere seriously with union. If a retractor be used, the final clearing of the bone is completed after it has been applied.

The older Surgeons cleaned the bone by scraping the periosteum up with the back of the knife. Most modern operators content themselves with stripping the muscles from the bone as high as may be necessary, and finally dividing the periosteum at the point at which the bone is to be sawn by a firm circular sweep of the knife from heel to point, first round the under surface of the bone, and then round the upper surface in the opposite direction. If there be two bones, care must be taken in clearing them in this way not to direct the edge of the knife upwards in the interosseous space higher than the line to which the saw is to be applied, lest any artery be cut where, on account of its retraction, it will be difficult to secure. Those, however, who are willing to sacrifice a little elegance and rapidity will find an undoubted advantage in carefully raising the periosteum with the muscles in retracting the soft parts. This is easily done by a periosteal elevator, so as to leave a tube of periosteum which will cover the end of the bone when the stump is closed, or may be previously brought over the end of the bone and secured in that position by a few catgut sutures. The advantages gained by thus saving the periosteum are not very evident if all goes well and the stump heals by first intention, but should suppuration occur and the bone protrude, it will be found that the end is completely covered by the periosteum, which becomes firmly adherent to it after four or five days. The medullary canal being in this way closed, the danger of septic osteomyelitis, necrosis and pyæmia, is greatly diminished. In cases healing without suppuration a rounded end to the bone seems to be formed at an earlier period than when the periosteum is not saved, and in the

forearm it prevents the union of the divided ends of the bones and ensures a considerable degree of pronation and supination in the stump.

The bone having been properly cleared and the soft parts firmly retracted, the saw is applied to the highest point exposed. In order to saw the bone quickly and steadily, the first cut should be made so as to form a deep groove to receive the teeth : to do this, the heel of the saw is steadied against the left thumb, which is pressed on the bone, and the whole length of the instrument is sharply drawn across the bone. The groove thus formed receives the edge of the saw : and the bone may then be quickly cut through by long, light, and sweeping movements of the instrument. The assistant must carefully support the part to be removed ; neither depressing it so as to snap the bone as it is weakened by sawing : nor raising it so as to lock the saw. In sawing a single bone the position of the saw is gradually changed from the horizontal to the vertical, the bone being then less likely to break if the limb be improperly supported. When there are two bones of equal strength in the limb, as in the forearm, they should be cut through at the same time ; but in the leg, the fibula, being the weaker, should always be first divided. Should the division be made irregularly, and splinters of bone project, these must be snipped off with cutting-pliers.

In performing an amputation, the preparations directed on page 40 must be accurately carried out. The Surgeon must see that the **Amputating Instruments** are in proper order, and of good construction. For the smaller amputations straight bistouries, narrow or broad in the blade according to the size of the part to be removed, will be required. Scalpels, also, not too broad in the blade, are useful in cases in which the bistoury, from its length, might be inconvenient. Cutting-pliers, with long, strong handles and short blades, either straight or curved, are especially required in amputations about the hands and feet. The knives for the larger amputations should have smooth ebony or steel handles, and be well balanced. The back of the blade should run straight to the point, and be well rounded. The edge should taper off towards the point, with a good convexity. The breadth of the blade should be from three-fifths to two-thirds of an inch, and its length should be proportioned to the size of the limb to be removed. In operating by transfixion in order to make a good sweeping cut, so as to form a well-rounded and smooth flap, the blade should as a general rule be about equal in length to double the diameter of the limb. For raising the flaps by dissection many Surgeons prefer shorter knives. The saw should be strong in the blade and buck so as not to bend in cutting. The blade must be of good breadth, and its teeth must be well set, so that it shall not hang as it works its way through the bone. Artery-forceps of the ordinary bull-dog kind, and torsion-forceps will be required ; and some dozen or more of forepressure-forceps should always be ready for the temporary arrest of hæmorrhage from the smaller vessels while the larger are being secured.

The Arrest of Hæmorrhage.—After the limb has been removed the first thing to be done is to restrain arterial hæmorrhage. The vessels are to be secured by some of the means described in Chapter XIV. The means most commonly adopted in the present day are torsion and ligature with prepared catgut or fine silk, which may be left in the wound without fear of after-trouble. Whatever means of arresting hæmorrhage are adopted, all vessels visible on the surface of the flaps should be secured before the tourniquet is removed, the

Surgeon being guided by his anatomical knowledge to the situation of the more important branches. In addition to the main trunk, from two to four or six smaller vessels usually require to be secured : but sometimes, either from the existence of malignant disease, or of extensive suppuration in the limb, the stump is excessively vascular, and a very large number of ligatures may be required. I have, in these circumstances, more than once had occasion to apply between twenty and thirty ligatures to vessels in the arm and thigh.

Free arterial bleeding will sometimes take place from a point in the cut surface of the bone, in consequence of the division of the trunk of the nutrient artery. This hemorrhage is best arrested by pressing into the canal one or two strands of carbolised catgut twisted together ; or, if this fail, it may be plugged with a small piece of carbolised sponge, which will become buried in the stump and absorbed almost as easily as the catgut. The old plan of inserting a wooden plug with a wire to it should never be resorted to if other means are available, as it is certain to serve as a centre of suppuration, and it causes disturbance of the wound when it is removed.

It is impossible to take too great care in arresting not only all arterial hæmorrhage, but all oozing of blood before closing the wound. It is to painstaking arrest of every trace of bleeding that the great success of some Surgeons in obtaining primary union is in part to be attributed. To have to open up the wound to secure a bleeding vessel within an hour of the operation is one of the most annoying accidents that can happen to a Surgeon, and is most damaging to the prospect of speedy union of the wound, but even this is less injurious than the distension of the flaps with a coagulum, the result of coozing which, perhaps, stops just short of obliging the Surgeon to open up the wound for its arrest.

Before closing the wound, the large nerves should be drawn out and cut short with scissors to prevent their becoming implicated in the superficial scar. Any projecting tendons should be cut short in the same way.

Closure of the Wound.—The hæmorrhage having been arrested, the covering is brought together over the bone by means of sutures. In a well-made stump the covering is so loose that no force is necessary to bring the edges together ; consequently, adhesive plaster can never be required. In cases in which a strictly antiseptic dressing is being used, unwaxed silk boiled for half an hour, and then soaked for twenty-four hours in a 1 in 20 solution of carbolic acid, makes the best sutures. If the dressing is such that decomposition of the discharges is possible, it is better to use silkworm gut, horsehair, or metallic sutures, as they do not absorb the septic matter, and are consequently quite unirritating if they are not tight. In inserting the stitches, it is better to put in two or three thick sutures, either of silk or wire, at intervals of about one inch to one inch and a half (Fig. 27). They should get a good hold of the skin and fat for at least one inch from the edge of the wound. These bear any strain that may arise from swelling or retraction. Between them finer sutures must be inserted, at intervals of about half an inch, bringing the skin edges into accurate apposition. Such close sewing as this, however, would somewhat endanger primary union, unless a proper exit for the discharges was provided for by drainage tubes. These are best made of india-rubber. One may be inserted in each angle of the wound, and, if it seems necessary from the size of the stump, a third may be placed in the middle. Drainage-tubes must be cut level with the surface of the wound, and above all it must

not be forgotten to fit each with a couple of threads, one on each side of its orifice, to prevent its slipping into the wound and being lost there, an accident which has frequently happened from neglecting this precaution.

Dressing the Stump.—An amputation leaves an incised wound which must be treated on those principles which are fully described in Chapter IX. These may be briefly summed up thus :—1. Complete arrest of hæmorrhage ; 2. Removal of all coagulum, bone-detritus, or other foreign bodies ; 3. Close and accurate coaptation of the surfaces of the wound ; 4. Efficient drainage ; 5. Perfect rest of the part ; 6. Asepticity of the wound. These objects may be attained by many modes of treatment, but perhaps by none more perfectly than by the absorbent antiseptic wool or gauze dressings now so commonly used. These by their uniform elastic pressure, support the stump, keep the surfaces of the wound in accurate apposition, and greatly diminish the exudation during the first twenty-four hours. They require changing infrequently, and in many cases the first dressing may be left on till the stump is practically

Fig. 27.—A Stump showing the mode of applying Suture and drainage-tube. A drainage-tube.

healed. In this way more perfect rest is given to the wound than by any other method of treatment. Some Surgeons, trusting to the elastic pressure of the dressing to diminish the exudation and to prevent its accumulation in the wound by maintaining perfect apposition of the surfaces, have given up the use of drainage tubes in all amputations through healthy tissues. It is, however, wiser, as a rule, to insert one or two short tubes which may be removed, if all goes well, at the first dressing. They give a greater certainty that no fluid shall accumulate between the flaps, and do not practically retard the healing of the wound. The necessity for drainage is greater if the wound be washed with a strong solution of carbolic acid before being closed, as this antiseptic seems considerably to increase the early serous exudation. The solutions of perchloride of mercury do this to a lesser degree. The details of the application of these and other antiseptic dressings will be found in the chapter on the treatment of wounds.

It must often happen, however, that the Surgeon is obliged to amputate through tissues which are already inflamed, or that he may not have at his command the materials necessary for the more perfect forms of antiseptic dressing. Under these circumstances it is essential that a proper provision be made for the escape of the discharges either by the use of drainage-tubes if they are at hand, or if they are not, by leaving a sufficient space between the

stitches and arranging the dressing in pads, so as to have the edges of the wound free. In the hands of some Surgeons the open treatment, that is to say, arranging the stump on a pillow without the application of any dressing has proved very successful. The late Mr. Callender obtained excellent results by the use of drainage-tubes for from twenty-four to thirty-six hours, and placing the stump on a well-padded splint, to which it was bandaged, so as to prevent all voluntary movement and disturbance from involuntary twitchings. The wound was dressed with lint soaked in carbolic acid and oil, and cleansed when necessary with a glass brush dipped in a spirituous solution of carbolic acid. In fact any method of treatment which secures the essential conditions of rest, drainage and asepsity will, if carefully carried out, be followed by success. The amount of rest that a stump gets depends to some extent upon the skill with which it is handled by the Surgeon at the dressing, but it is evident that the most perfect rest will be obtained by those methods of treatment which involve the least frequent change of dressing. Whatever dressing may be adopted, the stump must be supported on a soft pillow, and the weight of the bed-clothes taken off by a cradle; or should the covering be composed of heavy muscular flaps, it may advantageously be placed on a well-padded wire splint.

In some cases, although the flaps may appear abundant at the time of the operation, the retraction may much exceed that which was anticipated, and a wide granulating surface may be left after the deep parts have healed. This is most common in amputations in the thigh. If the covering has really been sufficient, this will usually remedy itself, the contraction of the granulating sore gradually bringing the skin edges together. The healing of the stump under these conditions is hastened by applying weight extension, which is done thus: a piece of diachylon plaster is cut of sufficient length to reach to the next joint above the amputation on the anterior and posterior aspects of the limb, and to form a loop extending at least one foot beyond the end of the stump. Its width at each end must be nearly half the circumference of the limb, but in the middle it may be somewhat narrower. The plaster is well warmed and applied to the stump, and surrounded by a few turns of a bandage made of the best elastic Welsh flannel. A wide "spreader," made of a piece of wood with a hole in it for the rope which supports the weight to pass through, is then put into the projecting loop of plaster. The spreader saves the end of the stump from being squeezed. The weight is then applied over a pulley in the same way as is described under the treatment of fracture of the femur. The results of this treatment are most satisfactory, especially in the lower third of the thigh.

In most cases the stump is benefited by the application of a bandage to support and mould it during the final stage of healing. After cicatrisation is completed, the patient may go about on crutches, but must not wear an artificial limb for some months, until the parts have become firmly consolidated; during the whole of this time the stump should be kept carefully bandaged, and not exposed to injury.

SIMULTANEOUS OR RAPIDLY CONSECUTIVE AMPUTATION OF TWO LIMBS for severe injury or for gangrene, has occasionally been successfully practised, either by two Surgeons performing the two amputations at the same time; or by the same Surgeon doing first one and then the other, the vessels of the first limb being secured by an assistant whilst the second limb is being removed. The circulation through both lower extremities may be completely arrested by

compressing the aorta with Pancoast's tourniquet. By means of this valuable instrument, I have amputated both thighs in close succession without waiting for the ligation of the arteries in that which was first removed. The object in two simultaneous amputations is to lessen the shock by throwing, as it were, that of the two operations into one. In doing this, however, the Surgeon must necessarily be guided by the circumstances of the case, for if the patient be very greatly depressed, the infliction of so severe an injury may extinguish life at once. Under such circumstances it is perhaps better to let the patient die in peace than to hasten his death by a hopeless operation.

STUMPS.

On examining the structure of a stump after one or two years have elapsed from the time of its formation, it will be found to be composed of a mass of fibrous and areolar tissue, any muscular substance which may have entered

Fig. 28.—Endings of Nerves in a stump.

into its formation having completely disappeared. Any tendons which may have been divided will be either lost in the fibrous tissue of the scar, or will have formed new attachments to the bones. The end of the bone is rounded and the medullary canal closed by a layer of compact bone. The bone itself is often atrophied, its compact tissue being thinner, and its cancellous tissue more spongy than in the corresponding part on the other side. The vessels are obliterated as high as the nearest branch and converted into fibrous cords. The ends of the nerves are bulbous (Fig. 28), the bulbs being composed of fibrous tissue, among which are great numbers of new nerve fibres twisted and rolled upon each other in all directions.

The proper adaptation of **Artificial Limbs** is a matter of considerable consequence; and the ingenious mechanical contrivances that are at the present day applied to stumps, leave little to be desired. The Surgeon had better leave the details of these mechanical contrivances to the instrument-maker; but he should see that they are made light, consistently with sufficient strength and support, and that the end of the stump is never injuriously pressed upon by them. Thus, after amputation of the thigh, the artificial limb should take its chief bearing point from the lower part of the pelvis and hip. In amputation immediately below the knee, this joint should be bent and received into the socket of the instrument; and, if the amputation be at a lower point than this, and the stump be extended into the artificial limb, its end must be protected from injurious pressure.

In all amputations of the lower limb in which the Surgeon has succeeded in producing a satisfactory loose covering, not adherent to the bone, and with the scar well behind it, the patient should be encouraged to bear part of his weight, at least, directly on the end of the stump. Not only does this give increased steadiness in walking, but it is said to diminish the tendency to excessive atrophy of the soft parts which sometimes occurs in old stumps. The plan recommended by Teale of gradually accustoming the end of the stump to bear pressure will be found most satisfactory. The patient must prepare a number of circular pieces of flannel of the same diameter as the socket of the artificial limb. He first puts in a sufficient number of these to form a pad

just touching the stump; after this he adds one daily till the stump becomes accustomed to bear the necessary degree of pressure. In all amputations through the knee-joint or condyles of the femur, and in Syme's or Pirogoff's amputation at the ankle, the patient should be able to bear his whole weight on the stump without difficulty.

MORBID CONDITIONS OF STUMPS.—**Septic osteomyelitis**, that is to say, septic inflammation of the medulla of the bone, when the canal has been opened in removing the limb, is one of the most serious accidents that can happen after an amputation. It most frequently occurs during the second week after the operation. The symptoms and pathology are fully described in the Chapter on Diseases of Bone. It was formerly a frequent cause of pyæmia, but with the present improved treatment of wounds it is very rare.

Necrosis.—It not unfrequently happens that a small scale of bone which has been injured by the saw dies, and is separated some three or four weeks after the operation. This is most common in those stumps which unite by

second intention, and in which the bone has been bathed in pus for some time. It is said, also, in some cases, to be due to the heat generated by too violent sawing. It is to be prevented by careful sawing, by saving the periosteum as described on page 71, and by the prevention of suppuration by careful antiseptic dressing.

More extensive necrosis used to be a frequent consequence of septic osteomyelitis, but under the improved systems of dressing it is comparatively rare. In such cases sinuses will be left leading to the necrosed bone, which usually separates three or four months after the operation, the stump then becoming firmly consolidated. The sequestrum in such cases presents the following appearances:—the lower part is thick and annular, and includes the whole thickness of the bone. It is smooth externally, where it has been covered by the periosteum.

Fig. 29. Necrosed and
separated from Stump.

About an inch or less above this it becomes thinner, is composed of the innermost part of the bone—that which surrounds the medullary canal—and is roughened externally, where it has separated from the adjacent healthy bone: above this it is spiculated and very irregular, becoming gradually thinner (Fig. 29). The part of the bone which escapes necrosis is inflamed, and, as a consequence of osteoplastic periostitis, new bone is deposited abundantly on its surface, leading to a great increase in its thickness, which can be recognised readily through the soft parts.

Conical or "Sugar-loaf" Stumps, as they are called, commonly form, either in consequence of the flaps having been cut too short, or from the soft parts not having been sufficiently retracted before the bone was sawn; but in other cases they may occur, though the stump has been skillfully fashioned, in

Fig. 30. Extreme case of Conical
Stump.

consequence of the soft parts, which have been the seat of inflammation and suppuration before the amputation, retracting during the process of healing, so as to denude the bone. In such cases as these, great retraction and contraction of the flaps may go on during cicatrisation, so that the bone may never be covered at all, but be exposed on the surface of an irritable ulcer; or, if the wound does heal, the cicatrix will be unable to support the slightest pressure without becoming ulcerated. In these circumstances, the only remedy consists in laying open the stump, and cutting off about three inches of the bone.

The patient, whose stump is represented in Fig. 30, was under the care of Christopher Heath. The arm had been amputated in the bush in South Africa for an accident. The protruding bone was completely covered by a thin cicatrix. In such cases as this when the patient is a young child, it is probable that the protrusion of the bone is in part due to the continued growth from the epiphysis without a corresponding increase in the soft parts.

Aneurismal Enlargement of the arteries of a stump is very rare. A typical case of this condition has been recorded by Charters Symonds, in which a small aneurism $\frac{3}{4}$ of an inch in diameter, formed about two inches above the twisted end of the artery after amputation at the knee for injury. The stump healed after prolonged suppuration. Nine weeks after the operation, and two weeks after healing, the sac gave way, and the blood burst through the scar.

Fig. 31. Aneurismal Varix in Stump.

The patient recovered after ligation of the artery above and below the sac. He had suffered severely from syphilis.

A communication between the divided ends of the artery and veins forming an aneurismal varix has also been occasionally observed. In one case described by Gudge, the communication was between the posterior tibial artery and the *venæ comites* after disarticulation at the ankle (Fig. 31).

Painful and Spasmodic Stumps.—The nerves in a stump naturally become somewhat bulbous (Fig. 28); and no material inconvenience results from this condition. But it occasionally happens that a considerable enlargement forms in connection with one of them, and attains the size of a cherry or a walnut; and, this being pressed against the end of the bone, the stump becomes the seat of intense pain of a neuralgic character, more particularly whenever it is touched, when a sensation like an electric shock is felt. In such circumstances, excision of this bulbous extremity of the nerve is necessary, and will effect a cure. Sometimes a nervous twig may become implicated in the cicatrix and be compressed by it. Here an excision of the painful part of the scar will remove the pain. Besides this form of painful stump, which may occur in the strongest and healthiest subjects, and is entirely dependent on local causes, there is another condition in which the stump becomes the seat not only of intense pain, but of continuous convulsive twitchings. This form of painful stump arises partly from constitutional causes, and most frequently

occurs in females, more particularly in those who are hysterical or have been subject to neuralgic pains elsewhere. In these cases the general cutaneous sensibility of the stump is increased: it is the seat of convulsive jerkings or twitches, and the pain is more or less intermittent, being increased under the influence of various emotional and constitutional causes. The treatment of this condition should be conducted on the general principles that will be fully discussed when we come to speak of neuralgia. No excision of the nerves of the stump, or even amputation higher up, is of any avail; the disease, being constitutional, will certainly return in each successive stump, until at last the shoulder or the hip may be reached without any permanent benefit to the patient.

Occasionally after amputation, when healing has been accompanied by supuration, a condition of chronic or subacute neuritis, with sclerosis of the nerve, is set up, which has a tendency to spread slowly but steadily upwards, finally, perhaps, leading to changes in the spinal cord itself. The symptoms and treatment are those of chronic neuritis, which will be described under *Injuries of Nerves*.

Recurrence of the Disease for which the Amputation was performed is not of uncommon occurrence in strumous diseases of bones and malignant tumours. In the former case, amputation higher up may be advantageously performed: but in the latter, it is justifiable only when there is no evidence of secondary growths in internal organs or in the lymphatic glands.

Fatty Degeneration of the muscles of a limb, arising from their disuse, gives rise to a peculiar appearance in the stump. During the amputation, the muscles look like pieces of yellow wax, and are firm, but no marked diminution in size has taken place: the fat deposited between the fibres having to some extent compensated for the loss of muscular tissue, so that the general size of the limb and fullness of the muscle are preserved. Union takes place in these circumstances, though somewhat slowly; at least, this has occurred in several cases in which I have observed this condition. In one of these I amputated the leg for disease of the foot of nine years' standing, and in another the thigh for disease of the knee of fourteen years' standing.

MORTALITY AFTER AMPUTATION.

The general causes of death after operations have already been considered; but we must now examine some special points connected with the relative mortality after amputations of different kinds, and the cause of the differences that exist.

Before commencing, however, it would be better in order, as far as possible, to avoid ambiguity, to mention and define the chief causes of death after amputation.

Shock is exhaustion of the nervous centres, the result of violent overstimulation by the powerful afferent impulse which arises from the injury done to the sensory nerves, either by the knife in amputation or by the injury which rendered the operation necessary. Death usually occurs, in fatal cases, within twenty-four hours. It is aggravated by loss of blood before or during the operation.

Coma is identical with very severe shock.

Secondary hæmorrhage, as a cause of death after amputations, is usually

limited to those cases in which the bleeding occurs more than twenty-four hours after the operation.

Sloughing of the stump from amputating through injured or diseased tissues is an occasional cause of death.

Septic Diseases.—This term is here used to include all those general or local affections which arise from putrefaction of the discharges of the wound, or from its infection with those specific diseases which are so commonly developed when decomposition of the discharges is not prevented, and too many patients suffering from open wounds are crowded together in too confined a space. The chief varieties are :—(a) *Pyæmia*, a general process in which a pyogenic virus (that is to say, a substance capable of setting up suppuration in any part in which it may lodge), derived from a local centre of suppuration, is disseminated through the body by the blood stream. It is characterised by the formation of secondary abscesses in the viscera, joints, and other parts of the body, accompanied by high fever. (b) *Septic infection*, which is the infection of the whole system by a virus derived from an unhealthy or foul wound. The virus multiplies in the blood and causes death without giving rise to secondary abscesses. (c) *Septic poisoning* or *Sæpæmia*, due to the absorption of the chemical products of putrefaction from a foul wound. The term "septicæmia" is used by many writers to include both septic infection and poisoning. (d) *Traumatic Fever*, which is a milder form of septic poisoning. (e) *Hospital Gangrene*, an acute spreading inflammation, terminating rapidly in gangrene of the affected part. (f) *Erysipelas*, an infective inflammation of a specific nature, spreading widely from the wound and accompanied by grave constitutional disturbance. (g) *Tetanus*, an infective disease in which a poison is generated locally in the wound, which, being absorbed, gives rise to fatal convulsions. All these diseases are to be attributed directly to foul wounds and overcrowding.

The *Congestive pneumonia* often mentioned as a cause of death after amputations, is most probably always merely an effect of septicæmia, pyæmia, or septic poisoning.

Lastly, one of the commonest causes of death in Hospital reports is *Exhaustion*. This term is used with excessive looseness. Some Surgeons seem even to employ it occasionally as synonymous with shock or collapse. In the majority of cases, however, it really means that the patient is gradually worn out by the profuse discharge from a suppurating wound, combined with chronic poisoning by the absorption of the chemical products of putrefaction. In others it means that the patient died from the effects of severe traumatic fever, of septic origin, commencing on the second day, before he had fully recovered from the shock of the operation. "Exhaustion" doubtless covers, therefore, many conditions which should fairly be included amongst septic diseases.

These causes of death may be divided into the preventible and the unpreventible, and theoretically it may be said that shock is the only one that is genuinely unpreventible. All the septic diseases may be prevented by thoroughly aseptic treatment of the wound, and by proper attention to hygiene. Practically, however, it is not always possible to avoid the "preventible" diseases. The state of the patient's health, the presence of septic complications, bad hygienic surroundings, or the absence of the necessary means for carrying out antiseptic treatment or avoiding overcrowding, may put it beyond the Surgeon's power to save his patient from causes of death which under more favourable circumstances are easily prevented.

The circumstances which specially influence the results of amputations may be divided into three groups:—I. Those that have reference to the constitutional condition of the patient; II. The occurrence of Shock and Septic Diseases; and III. Certain conditions special to the operation itself.

I. In the first class the most important are 1, the *Age*; and 2, the *General Health* of the patient.

1. **Age** exercises an important influence on the result of amputations. As a general rule it may be stated that, the younger the patient, the greater the likelihood of a successful result, though very young children bear loss of blood badly. In youth there is a greater power of resisting the invasion of pathogenic organisms and of withstanding the effects of septic poisoning and loss of blood. The feebler tissues of old people are more readily invaded by pathogenic organisms, and suffer more severely from the irritating effects of the products of putrefaction. The introduction of Antiseptic treatment of wounds has, however, greatly reduced the dangers of amputations after middle life. Volkmann published the results of 48 cases of major amputations performed in patients above 50 years of age. He excluded from consideration all cases in which the amputation was performed during septicæmia, all double amputations, and some few cases in which the patient died from causes independent of the operation. Of the 48 only 2 died: 1 of tetanus, and 1, an habitual drunkard, 80 hours after the operation. The patients' ages were, in thirty cases between 51 and 60; in thirteen, between 61 and 70; in four, between 71 and 80; and one patient, aged 84, recovered from an amputation at the knee. Although the exclusion of all complicated cases makes these statistics more favourable than they would otherwise have been, the results show that under the improved treatment of wounds, a fair degree of success may be obtained even in very advanced life, provided that old age is the only unfavourable condition present.

2. The **General Health** of the patient previous to the operation exercises a most powerful influence on the chances of recovery. The state of the kidneys, more especially, is of great importance; for no condition tends more certainly to a fatal termination than chronic disease of those organs. The results of amputation necessarily differ widely, according as the operation is practised on the healthy inhabitant of a country district, or on the enfeebled and debilitated denizen of a large town.

II. 1. The occurrence of **Shock**.—Out of a total of 681 amputations collected from the reports of some of the Metropolitan hospitals between 1866 and 1872, 239 deaths occurred, and of these almost exactly 10 per cent. were due to shock. Out of 80 consecutive cases at University College Hospital during the same period, 8 died from shock. This cause of death is not under the control of the Surgeon, and it can hardly be hoped that the rate of mortality due to it can ever be materially diminished. The influence of shock is necessarily most felt in primary amputations. Indeed, its fatal results are almost confined to amputations performed within twenty-four hours of the infliction of the injury. It occurs in exact proportion to the severity of the injury, the amount of loss of blood, and the age of the patient. It is often preferable rather to the injury than to the operation; and it becomes a question whether, in many cases of hopeless smash of a limb, it might not be better to let the patient die in peace than to subject him to the repetition of a shock which he will be utterly unable to endure. This is more especially the case

in extensive crush of the lower extremity up to or above the middle of the thigh, such as is not uncommon from railway accidents. Amputation through the upper third of the thigh, or at the hip-joint, is then the only available operation, and it is often done: but I am not acquainted with a single case in which it has succeeded in men who have arrived at full maturity. In children and young adults it has proved successful.

As death from shock, after primary amputations, happens usually within twenty-four hours of the performance of the operation, it cannot in any way be affected by the conditions to which the patient is exposed after the operation, so far at least as hospitals or other external influences are concerned. We may, therefore, look upon death from shock as a part of the accident to which the person has been exposed, aggravated, doubtless, by the further depressing influence of the operation. Death from shock necessarily occurs more frequently under similar conditions of injury at advanced than at early periods of life. It is interesting also to observe that season exercises an influence on the liability to death from shock after primary amputations. According to Hewson, of Philadelphia, it is most fatal in winter, the cold, to which the sufferer has been exposed after the accident, acting as an additional cause of depression.

The only way therefore to diminish the proportion of deaths from shock is not to amputate in hopeless cases in order to give "a last chance" to a patient whose vital powers have already been depressed to the lowest ebb by a fearful mutilation. Such amputations which sometimes consist in little more than the severance of a limb still attached to the trunk by shreds of muscle, ought scarcely to find their way into a statistical table professing to give the results of operations the majority of which are performed more deliberately, and with a better prospect of success. They ought, in fact, to constitute a class of cases apart; the more so, as they are frequently complicated with internal injuries which are not detected until after the death of the patient.

Shock, as has already been shown, exercises its influence chiefly in primary amputations, far less in secondary ones; and disappears entirely as a cause of death, in pathological amputations, except in a few cases of such operations as amputation at the hip-joint or shoulder-joint in patients already greatly enfeebled by disease.

2. **The development of some form of "septic disease,"** is, however, far more important than shock as a cause of death after amputation, first because in former times these diseases proved fatal in a considerable proportion of all cases operated on, and secondly, because they are to a great extent, if not altogether, preventible. The terrible frequency of these diseases a few years ago is shown by the fact that out of the 631 cases of amputation before mentioned no fewer than 86 died from one form of septic disease alone—pyæmia—irrespective of those who are reported as having died of "exhaustion," septicæmia, erysipelas, and "low cellulitis." Of the 80 cases from University College Hospital ten died of pyæmia alone. The influence of this disease on the death-rate was found not only to vary greatly according as the operation was primary, secondary, or for disease, but also to differ considerably in different hospitals. Above one-third of the deaths amongst the primary amputations were from this cause. In the secondary amputations 44.4 per cent. of the deaths were from pyæmia, and in those for disease 34.6 per cent., an amount nearly equal to that of the primary operations.

The foregoing statements justify us in believing that, if septic diseases could be prevented, no patient, who at the time of the operation is in good general health, should die of an amputation if he survive the period of shock, unless it be from the weakness of extreme old age. Secondary hæmorrhage is almost as preventible as pyæmia by the exclusion of septic influences. The value of the majority of amputation statistics is greatly impaired by all the cases being put together with no further separation than into primary and secondary, and we thus get a very false notion of the mortality occurring in ordinary cases. Some very valuable statistics have been published by Max Schede, in his work on Amputations, in which this source of error has been eliminated by following the classification of cases suggested by Volkmann. The cases are divided first into "Complicated" and "Uncomplicated." The Complicated cases, which are classed separately, are—Multiple or Double Amputations; cases complicated with other severe injuries; cases in which the patient was suffering from severe surgical fever, septicæmia, pyæmia, spreading gangrene, or tetanus, at the time of the operation; and, lastly, cases which terminated fatally, or in which the cure was incomplete after many months, on account of acute intercurrent diseases, such as delirium tremens, acute pneumonia (not of septic origin), or chronic diseases, such as phthisis, Bright's disease, amyloid degeneration, secondary cancer, &c.

Secondly, the cases are divided into those treated antiseptically and those belonging to a period before the introduction of antiseptics and systematic drainage into the treatment of amputation wounds. The former are taken from the published statistics of Socin of Bâle, Volkmann of Halle, and Max Schede in Berlin; the latter from those of Bruns of Tübingen, Bardeleben, men of Greifswald, and Billroth, then of Zurich. The cases treated by the older methods showed the following results:—

	CASES.	DIED.	PER CENT.
Uncomplicated cases	377	110	29.18
Double amputations	10	3	30.00
Complicated by other injuries	5	4	80.00
" by Septicæmia, Tetanus, &c.	48	40	83.33
" by constitutional diseases	21	21	100.00
Total	461	178	38.83

These are not worse than the average statistics of amputations twenty or thirty-five years ago.

The cases treated antiseptically by carbolic acid dressings and all the precautions recommended by Lister, show the following results:—

	CASES.	DIED.	PER CENT.
Uncomplicated cases	321	14	4.4
Double amputations	13	3	23.8
Complicated by other injuries	11	8	72.72
" by Septicæmia, Pyæmia, Tetanus, &c.	45	30	66.66
" by constitutional diseases	27	16	59.26
Total	417	71	17.02

The causes of death in the uncomplicated cases are equally instructive:—

CAUSE OF DEATH.	OLD TREATMENT. 877 Cases.	ANTISEPTIC TREATMENT. 321 Cases.
Pyæmia	72	0
Septicæmia	19	1
Erysipelas	2	1
Tetanus	0	1
Pyæmia simplex	6	1
Secondary hæmorrhage	3	1
Old age	2	1
Shock	6	8
Total	110	14

The disease classed here as pyæmia simplex is blood poisoning, arising from a suppurating wound without the formation of secondary abscesses. It would be classed by many authors as septic infection.

Results even superior to these have been obtained at Newcastle-on-Tyne Infirmary by the use of antiseptics. Frederick Page has published the results of all the amputations performed in that institution from 1878 to 1891. They amount to 687, with a death-rate of only 8 per cent. The cases are not classified in the way above mentioned. If this were done, the death-rate in the uncomplicated cases would be probably less than 4 per cent.

The following are the statistics of amputations performed in University College Hospital during the twenty years 1871 to 1890 inclusive. They are divided into four periods of five years each. In the first period the majority of the cases were treated without antiseptics. In the last period every case was dressed with some efficient antiseptic dressing. The particular antiseptic used varied in different cases. Many stumps were most successfully treated by lasting dressings of iodoform or salicylic wool.

Deaths per cent.		27.5		24.29		18.08		11.78

The causes of death amongst the uncomplicated cases were as follows :—

CAUSES OF DEATH.	1871-1875.	1876-1880.	1881-1885.	1886-1890.
Pyæmia	9	4	0	0
Septicæmia	3	7	2	0
Erysipelas	1	0	0	0
Shock	5	5	3	2
Exhaustion	1	0	1	0
Sloughing of stump	3	2	2	0
Secondary hæmorrhage	0	1	2	0
Cardiac thrombosis	0	0	1	0
Tetanus	0	0	1	0
Total	22	19	12	2

Of the 17 fatal cases in the third period five were amputations at the hip-joint and two at the shoulder-joint. The two deaths in the uncomplicated cases in the last period were after amputation at the hip-joint.

These tables show a satisfactory and progressive diminution in the death-rate, especially in that arising from septic diseases. In fact, there has not been a death from pyæmia after amputation in University College Hospital since 1880. Another interesting feature in these statistics is the great diminution in the number of secondary amputations in the last ten years, showing the success that has attended the treatment of compound fractures. The total number of amputations has also considerably diminished; by no less than 30 per cent. if we compare the last five years with the first. This also is evidently in great part due to the success attending conservative surgery after injury. The amputations for disease have also considerably diminished in proportion to the patients admitted, for in 1879 about twenty surgical beds were added to the hospital. The number of amputations for disease of the knee is, in the last period, only half what it is in the first—another evidence of the advance of conservative surgery.

The amputation mortality in my wards, from 1850 to 1873, was 40·7 per cent. for injury and 18·1 for disease, on an aggregate of 387 cases, being 25·8 per cent. for all cases.

Although the improvement that has taken place generally in the amputation mortality is no doubt chiefly due to the employment of antiseptics, the better hygienic arrangements of modern hospitals cannot be ignored as a factor in lessening the liability to the generation of septic diseases. Many Surgeons also, who have not adopted any special antiseptic method of treatment, have achieved, by a careful selection of cases, by improved methods of operating, by perfect drainage and rest, and great attention to cleanliness, results which have rarely been surpassed. Spence, of Edinburgh, had once a run of 63 consecutive amputations with only three deaths. Amongst the most excellent results of this class that have been published, are those of Borland, of Kilmarnock, who out of 25 major primary amputations (double amputations being excluded), had 6 deaths, or 24 per cent., and in 63 amputations, secondary and for disease, only 2 deaths, or 3·1 per cent. These results were obtained without chemical antiseptics, by avoiding the use of water during the operation, the blood being wiped away with pieces of clean rag, and by leaving the wound to glaze before bringing the flaps together, with perfect rest of the stump, which was dressed with a thin piece of rag smeared with lard, any discharge that formed being wiped away.

III. The circumstances connected with the amputation itself that influence materially its result are : 1. Its *Seat*. 2. The *Structure of the Bone* sawn. 3. Whether for *Injury* or *Disease*. 4. If for disease, the *Nature* of the affection. 5. If for injury, the *Time* that has elapsed before the operation.

1. With regard to the influence of the **Seat** of amputation on the result as a general rule, the risk increases with the size of the part amputated, and as the line of amputation approaches the trunk : in fact, the nearer it is to the trunk, the greater is the danger. This is clearly shown by the subjoined table, derived from the statistics of amputation in various British, Continental, and American hospitals.*

SEAT.	CASES.	DEATHS.	PER CENT.
Shoulder-joint	117	58	49.5
Arm	1319	375	28.4
Fore-arm	1059	109	10.2
Hip-joint	46	19	41.3
Thigh	3477	1221	35.2
Leg	3003	985	32.7

The death-rate in the above table is higher for each operation than it would be at the present time, as the following statistics from University College Hospital serve to show :—

SEAT	CASES.	DEATHS.	PER CENT.
Shoulder-joint	19	6	31.6
Arm	30	4	13.3
Fore-arm	49	8	16.3
Hip-joint	16	12	75.0
Thigh	151	35	23.1
Leg	100	11	14.0
Ankle	42	2	4.7

The higher death-rate in the amputations of the fore-arm was due to the fact that two were cases of disease in extreme old age, and two were performed as a last chance of saving a case of tetanus.

If we turn to the records of military surgery we find similar results. In the war of the American rebellion the percentages of mortality were as follow, showing markedly how rapidly it runs up in accordance with the size of the part removed : fingers and hand, 1.6 ; wrist, 5.5 ; fore-arm, 16.5 ; arm, 21.2 ; shoulder, 39.2 ; partial of foot, 9.2 ; ankle-joint, 13.4 ; leg, 26 ; knee, 55 ; thigh, 64.4 ; hip, 85.7.

Not only is there this increase in the rate of mortality as the operation approaches the trunk, but in the larger limbs, more especially in the thigh, every additional inch that is removed appears to make a difference in this respect. Thus, in our army in the Crimea, of 178 amputations of the thigh, 44 were in the upper third, and of these 38, or 86 per cent., proved fatal ; 68

* The reader who may wish for fuller details of the statistics of amputations in the past and in modern times, may refer to the Tables published in the last edition of Cooper's "Surgical Dictionary," by Mr. James Caird, Sir J. Y. Simpson's "Lectures on Hospitalism," M. Chenu's elaborate reports on the Medical Service of the French Army in the Crimean War and in the Italian Campaign, the Official Reports of the United States Army in the War of the Rebellion ; and Max Schede's work on "Amputations" in Billroth and Pitha's Surgery.

were in the middle third, and of these 41, or 60 per cent., died; whilst in the lower third the mortality out of 66 cases was 37, or 56 per cent.

The size of the part removed and its proximity to the trunk have also considerable influence on the cause of death. Thus after the smaller amputations death occurs only in unhealthy states of the constitution, or from the occurrence of erysipelas, or of some other infective process originating in the wound. In the larger amputations in addition to these causes of death, shock is frequently fatal, often aggravated by loss of blood before or during the operation. The larger the vessels divided the more likely is secondary hæmorrhage to occur.

2. The **Part of the Bone** that is sawn through may influence the result. Whenever the medullary canal is opened, if the patient be exposed to bad hygienic surroundings, and putrefaction of the discharges be not prevented, there is danger of septic suppuration taking place in the medulla, a condition very frequently followed by pyæmia. Amputations through the cancellous ends of long bones are comparatively free from this danger, and consequently show a lower mortality. In disarticulations this complication can hardly occur.

3. The mortality resulting from amputations is influenced to a great extent by the **Cause** for which the operation is performed, being far greater in corresponding parts after injury than after disease. The fore-arm and ankle, however, seem to be exceptions to this rule, for the reason that amputations in these regions cause little shock, and the vessels divided are small, and secondary hæmorrhage is rare. Thus two important causes of death are eliminated, and a healthy patient usually recovers. When the amputation is performed for disease, however, it is most commonly in cases of tuberculous caries, in which, owing to the general condition, other means have failed to cure.

The following table gives the result of numerous cases in civil practice, collected from various sources. (See note, p. 86.)

SEAT.	<i>Injury.</i>			<i>Disease.</i>		
	CASES.	DEATHS.	PER CENT.	CASES.	DEATHS.	PER CENT.
Thigh	264	576	59.7	1465	477	32.5
Leg	771	356	46.1	1281	301	23.5
Arm	514	180	34.4	250	65	26.0
Fore-arm	360	38	10.5	151	23	15.9

The following statistics from University College Hospital, being of more recent date, show somewhat better results:—

SEAT.	<i>Injury.</i>			<i>Disease.</i>		
	CASES.	DEATHS.	PER CENT.	CASES.	DEATHS.	PER CENT.
Hip	2	1	50.0	14	11	78.4
Thigh	31	12	38.7	120	23	19.1
Leg	44	9	24.5	56	5	8.9
Ankle	6	0	0	36	2	5.5
Shoulder	6	3	50.0	13	3	23.0
Arm	20	1	5.0	10	3	30.0
Fore-arm	24	1	13.3	25	4	16.0

The *Shock* inflicted by the injury, with its subsequent evils, is the principal reason for the greater mortality after amputations for injury than after those for disease. After amputation for injury, also, there is a greater liability to the occurrence of gangrene of the stump, as the incisions may be carried through tissues which, though apparently sound, may be so bruised as to be beyond recovery. Pyæmia, formerly as frequent in primary as in secondary amputations, should now be equally rare. Exhaustion is more frequent after removal of a limb for disease, as in many cases the operation is necessarily performed on patients already weakened by long illness. In many forms of disease, however, especially in affections of bones and joints, it will be found that those patients do best in whom the disease is most chronic.

4. The **Nature of the Disease** for which the amputation is performed influences its mortality. Amputations for malignant growths are more fatal than those for diseased joints. This is probably due to the fact that the malignant growths have often given rise to secondary growths in the viscera before the operation was performed. In amputation for tubercular diseases of bones and joints similar disease of the internal organs is not uncommonly found should death occur. When a limb is removed for acute septic suppuration of a joint, a fatal result is of frequent occurrence, especially if the affected articulation be a large one, such as the knee. In these cases the patient is usually suffering from severe febrile disturbance, the result of absorption of septic matter from the diseased joint, and amputation under such circumstances is frequently followed by fatal septicæmia. But when the disease has once become chronic, the precise period at which the amputation is performed exercises but little influence on the mortality, provided it be not deferred to too late a stage, when the patient's constitution is worn out by hectic.

Amputations of expediency—those performed for the convenience of the patient, as in cases of talipes or ankylosis—have been said to be especially fatal. Bryant, in 1859, showed that at Guy's Hospital, death had followed in 40 per cent. of these amputations in the lower extremity. There is no reason, however, to believe that this is true of such amputations at the present time. In fact, as such amputations must necessarily come into the uncomplicated class, a fatal result ought to be a rare and exceptional occurrence.

5. In amputation in case of injury an important question has to be determined, viz., the influence exercised by the **Time** that has elapsed from the infliction of the injury to the performance of the amputation. Not only the rate of mortality, but the conditions that immediately occasion the fatal event, are influenced by the period at which the operation is performed.

Amputations for injury are commonly divided by Surgeons into *Primary* and *Secondary*; the *primary* being those that are performed during the first twenty-four or thirty hours, before any spreading inflammation or traumatic fever has developed itself. By *secondary* amputations many Surgeons mean those operations that are practised after the first twenty-four hours; whilst others again more correctly restrict the term to those that are done after suppuration has been fully established, and the surgical fever is beginning to subside as granulation tissue springs up to present a barrier to the absorption of the septic poison. Those who thus limit the use of the term *secondary*, call all the operations performed between the end of the first day and the period of full suppuration "*intermediate*." The distinction is of some importance, as operations performed during high surgical fever are extremely

fatal. In the following tables, the cases are divided merely into primary and secondary. The first is from my own practice at University College Hospital. During the last fifteen years, owing to the great success attending the antiseptic treatment of compound fractures, secondary amputations have been so rare that no statistics of any value can be added. The cases in the second table have been collected from various sources, and refer to civil practice before 1870.

RESULTS OF PRIMARY AND SECONDARY AMPUTATIONS IN CASES OF INJURY,
AT UNIVERSITY COLLEGE HOSPITAL. (1869.)

SEAT	Primary.		Secondary.	
	CASES.	DEATHS.	CASES.	DEATHS.
Thigh	14	8	21	14

Shoulder and Arm	6	2	5	2
Fore-arm	6	0	1	0
Total	48	18	43	19

SEAT.	Primary.			Secondary.		
	CASES.	DEATHS.	PER CENT.	CASES.	DEATHS.	PER CENT.
Thigh	235	153	65.1	156	85	54.4
Leg	405	178	43.9	150	72	48.0
Arm	276	79	28.6	75	32	42.0
Fore-arm	190	16	8.4	27	6	22.2
Total	1106	426	38.5	408	195	47.7

When we consider that the secondary amputations are almost exclusively derived from cases in which an attempt to save the limb has failed on account of extensive sloughing of the soft parts, gangrene of the limb from injury to the vessels, profuse suppuration, septic osteomyelitis, necrosis of the bones, or threatened death from exhaustion or septic poisoning, it is not surprising that they are followed by a higher proportion of deaths than primary operations. In primary amputations high up in the thigh for injury, shock, more due to accident than the operation, is so commonly fatal, that the proportion of deaths is higher for primary than secondary amputations in this region. We must not conclude, however, that the patient's chance of life would be increased by leaving the mangled limb on in the hope of his surviving to a secondary amputation. Death from shock would probably occur, as the presence of the limb would prevent rallying and be as fatal as the operation. In any secondary operation, should the patient survive the period of shock, the condition of the limb at the time of amputation necessarily increases the risk of pyæmia, septicæmia and secondary hæmorrhage. The deaths from these causes are therefore more common in secondary amputations, while shock is more frequent in primary operations.

In military practice, secondary amputation is also more fatal than primary. In the British army in the Crimea, the relative rates of mortality per cent. after primary and secondary amputations, were as follows:—after *primary*

amputations at the shoulder, 26 ; of the arm, 17 ; of the fore-arm, 3 ; of the thigh, 62 ; of the leg, 30 ; and of the foot, 17 ; after *secondary* amputations at the shoulder, 66 ; of the arm, 31 ; of the fore-arm, 28 ; of the thigh, 80 ; and of the leg, 76. That is to say, for the upper extremity, the whole rate of deaths after primary was 15, against 41 after secondary amputations ; whilst, for the lower extremity, excluding the foot, it was 46 per cent. for the primary, as against 78 for the secondary. In the American army during the Civil War, the mortality after primary amputation of the thigh was 54·13 per cent. ; and after secondary amputation, 74·76. It will be noted that the primary amputations of the thigh are far less fatal than the secondary, the reverse of the relative proportions met with in civil practice. The explanation of this is probably that the shock caused by a bullet-wound is less than that following the severe crushes common in civil practice, as for example that caused by a railway accident. Primary amputations in military practice are moreover frequently done on the field of battle, and the patient is treated in a tent or in a pure house ; secondary operations are more often performed in crowded hospitals or in houses ill adapted for the purpose, which have been overfilled with wounded for a week or ten days after the battle. The primary amputations are in great part healed before the effects of overcrowding and accumulation of suppurating wounds become fully developed ; the secondary operations are performed just when these evils are reaching their maximum. In future wars it is to be hoped better results will be obtained by the use of antiseptics, but it is hardly to be expected that overcrowding and foul wounds can be altogether avoided ; and under these circumstances the Surgeon will do better for his patient by giving him the benefit of a primary amputation in every doubtful case, than by attempting to save the limb trusting to a secondary operation in case of failure.

SUMMARY.—On reviewing the whole subject of the causes of death after amputations, we cannot but come to the conclusion that the mortality is influenced chiefly by the success or failure in the prevention of septic processes in the discharges of the wound, and by the hygienic conditions to which the patient is subjected after the operation. The evil influences arising from exposure to an atmosphere vitiated by the emanations from the decomposing discharges of suppurating wounds, and to those various combinations of conditions that are summed up under the general term "*Hospitalism*," have so important a bearing upon the death-rate after amputation, that, in order to arrive at a just estimate of the probable chances of recovery in any given case, it becomes necessary to consider not only whether the operation be done for injury or disease—whether it be primary or secondary—whether the disease be simple or malignant—whether the patient be aged or young, healthy or diseased ; but, above all, whether, after the removal of the limb, the patient will be exposed to those conditions that result from the aggregation of the sick and the crowding together of foul suppurating wounds.

Whatever explanation we may give of the fact, it remains certain and incontrovertible that the rate of mortality after amputation of all limbs in the large city hospitals of Great Britain up to a comparatively recent period has been at least 1 in 3. In those of Paris, out of 1,656 amputations, the statistics of which were collected by Malgaigne and Trélat (Simpson), 803 died, or nearly 1 in 2. The Government statistics collected by Bristowe and Holmes

show that in 1861 the amputation death-rate in Parisian hospitals was 3 in 5, and more recently Le Fort gives the mortality at 58 per cent. In Germany matters were no better. Billroth's published amputation mortality was at one time from 43 to 46 per cent. In the United States, however, the death-rate was much smaller; the mortality in the Pennsylvania Hospital being only about 24 per cent., and that in the Massachusetts General Hospital 26 per cent.

In military practice, the result of the experience deduced from the mortality following amputations during the great modern wars is at least equally unfavourable. But here there are so many modifying and disturbing elements that it may be well to exclude these cases from consideration.

In fact, then, on taking the average mortality after amputation in the largest hospitals in the great centres of civilisation, we come to this result, that it commonly varied from 60 to 35 per cent., and did not fall below 24 per cent.; and that in certain of the larger amputations, as in the upper third of the thigh and at the hip-joint, it ran up to from 70 to 90 per cent. Widely extended statistical returns showed but too plainly that these figures were trustworthy and constant.

So constantly did these figures come out in hospital returns, that Surgeons had almost come to regard them as representing the necessary, or, so to speak, the *natural* rate of mortality after amputations. But that it was not necessary—that it was dependent on preventible causes, was maintained by Callender, Lister, Spencer, and others who, by different methods of treatment, but all having in view attention to the hygienic conditions of the wound and of the patient, obtained results far better than those formerly prevailing. Such results are now no longer exceptional.

The statistics quoted in a former page from Max Schede's work on amputations show what can be accomplished by the antiseptic treatment. The system adopted by the Surgeons, from whose practice those statistics were collected, was that recommended at the time by Lister. It matters little, however, what method of dressing is adopted, so long as the decomposition of the discharges is absolutely prevented. This is the principle of antiseptic surgery; but the best means of carrying it out has probably yet to be discovered. Whenever antiseptic treatment is efficiently carried out, by whatever means it may be accomplished, the wound ceases to be a source of infection and of contamination to the surrounding atmosphere, and the results of hospital practice then equal the best that can be obtained in private.

Up to 1869 Surgeons had no opportunity of obtaining a knowledge of the results of amputations on a large scale, except such as had been furnished by the statistical reports of hospitals; but in that year Sir James Simpson collected from small country hospitals, and from private practice in manufacturing and mining districts, in which amputations are of common occurrence, statistics which proved satisfactorily that in the time before the modern improved methods of treating wounds were fully understood, the aggregation of patients suffering from open wounds in one building exerted a powerful influence on the proportion of deaths.

Simpson collected the particulars of 2,098 amputations of all kinds occurring in the country and in private practice in towns; of these 229 died, or 1 in 9·2; and of an almost equal number, viz., 2,089 amputations, performed in the large city hospitals of Great Britain, 855 died, or 1 in 2·4.

It is probable that Simpson's figures were not absolutely but only approximately correct, and that certain sources of fallacy had intruded themselves, more especially with regard to the condition of the patient *before* the operation, to which undoubtedly great importance must be attached (*vide* p. 81). But still, making full allowance for all this, the difference between the two sets of cases is so great, that the conclusion that the mortality after amputation in hospital practice was nearly four times as great as when the same operations were performed out of hospital, cannot be very materially affected; and it was impossible to escape from the inference that the high hospital mortality was greatly influenced by the exposure of the patient to those septic conditions existing in the air of large hospitals, which have been so ably and graphically described by Parkes, and which exercise the most injurious effect on patients with large wounds who are exposed to them.

That in the absence of efficient antiseptic and hygienic precautions those septic influences may eventually saturate hospitals, and exercise a most important influence in causing fatal pyæmia, septicæmia, and osteomyelitis, after amputations, from which, as has already been shown, a large proportion of those operated on formerly died, is evident from the following considerations:

1. From the commencement of this century up to a comparatively recent period—during what, in fact, may be termed the pre-antiseptic age—no improvement had taken place in amputation mortality in hospitals.

2. The prevailing high rate of mortality varied greatly in different hospitals in the same town, in which the patients were of the same class of society, followed pretty much the same occupations, and were subjected to the same kinds of injuries and diseases; the hospitals being officered by Surgeons of equal professional skill, and the only inequality existing being in the different conditions to which the patients were exposed in different hospitals.

3. The difference in the amputation mortality in different London hospitals varied from 18 and 25 to 47 per cent. In Calcutta, the death-rate after thigh amputations varied in different hospitals from 42 to 80 per cent. (Downie).

4. Of late years, this excessive amputation mortality has been greatly reduced in all hospitals.

5. This reduction is contemporaneous with, and, *as all the other conditions continue as before*, is dependent upon, the employment of antiseptics in the treatment of wounds, and the greater attention paid to hospital hygiene.

6. In military practice, the rate of mortality after amputation has been found to be in the direct ratio of the aggregation of the wounded; and infective processes of septic origin may to a very great extent be averted by isolation of the patients.

CHAPTER III.

SPECIAL AMPUTATIONS.

THERE are, as has already been stated at pp. 59, 61, 70, three distinct methods of amputating limbs, viz., the flap, the circular, and the oval. A skilful surgeon will be able to produce a satisfactory stump by any one of the three methods, and it is desirable that he should be able to practise all. For although, as a general rule, one method may be more applicable than another, yet exceptional cases occur in which it may be advantageous to depart from the method usually adopted, and employ one of the others. In fact, the Surgeon should select that which is most suitable to the circumstances of the case before him. The flap method, or the combined flap and circular, is that to which most Surgeons give the preference in this country.

In describing any method of amputating, precise rules may be laid down for its performance through sound structures; but it often happens, especially in cases of injury, that the destruction of tissue is so irregular as to compel the surgeon to shape his flap as best he may from the uninjured parts; but so efficient is the moulding process of nature, that provided sufficient covering be left on the muscles and bones, a stump that at first looks irregular and unsurgical, will soon acquire a regular outline, and may be eventually in all respects as useful as one fashioned at first more artistically.

AMPUTATIONS OF THE HAND.—The **Fingers** often require amputation for injury or disease, more especially as the result of bad whitlow. When the ungual phalanx becomes necrosed, it may usually be removed without amputation, by an incision through the pulp of the finger, thus saving the nail and pulp, which will form an excellent end to the finger. If the operation be done in early childhood, a new and movable phalanx may form. Should amputation be required, it may either be done by opening the joint from its dorsal aspect with a narrow-bladed bistoury, and making the flap from the palmar aspect by cutting from within outwards: or the flap may be made from the palmar surface by transfixion, and the joint opened from the dorsal aspect (Fig. 33). In amputating the ungual phalanx from the dorsal aspect, the Surgeon must stand behind the hand: the finger must be flexed forcibly, so that the last phalanx is at a right angle to the next. The incision to open the joint must be made in continuation of an imaginary line drawn along the side of the second phalanx, midway between the dorsal and palmar aspects. It must commence at the base opposite the joint, and finish at the corresponding point on the other side, the Surgeon cutting from his left to his right side of the finger. As the joint opens, the lateral ligaments must be touched with the point of the knife. As these are divided, the first two phalanges must be extended while the ungual phalanx is still further flexed. The knife is then passed with a sawing motion towards the palmar surface of the phalanx, the edge being turned slightly

towards the bone. Finally the ungual phalanx is to be fully extended, and a flap cut including the whole pulp (Fig. 32). When any difficulty is experienced

Fig. 32. - Amputation of Part of a Finger by cutting from Above.

Fig. 33. - Amputation of a Finger. Cutting the Flap by Transfixion.

in finding the point, it is either from taking a wrong line, or from the presence of a small rheumatic exostosis on the base of the ungual phalanx.

In amputating by transfixion from the palmar surface, the finger must be

extended with the palmar surface towards the Surgeon. The knife must be made to transfix the finger as close to the bone as possible, and in such a way that the back is one-eighth inch on the distal side of the crease corresponding to the joint. A flap of sufficient length is then cut, which must be raised and held out of the way by an assistant. The joint is then opened, the operator leading the last phalanx forcibly backwards to put the anterior ligament on the stretch. Finally, the phalanx is removed by carrying the knife through

FIG. 34. Amputation of a Finger. Removing the Head of the Metacarpal Bone.

the joint, no flap being made from the dorsal aspect (Fig. 33).^{*} In doing this one must be taken to avoid cutting too high up and so mistaking the depression above the head of the second phalanx for the articulation.

Amputation is performed between the proximal and second phalanges in the same way; but as a stump composed of the first phalanx is of but little use, it is more common to remove the whole finger. In the hand of a working

^{*} For the Conservative Surgery of the Hand, *vide* chapter xlvii.

man, however, it is better to save even one phalanx, as it helps somewhat to strengthen the grasp; for the stump can be strongly flexed, partly by the action of the interossei and partly by the long flexors which form new attachments at its extremity. In the case of the index finger, it will be better always to leave the proximal phalanx, the stump of which forms a useful opponent to the thumb.

Amputation is frequently required at the **Metacarpo-phalangeal Articulation**. Here it may be done in two ways: either by lateral flaps, or by the oval method. If by *lateral flaps*, the adjoining fingers should be well separated from the one about to be removed, by an assistant who grasps the hand, so as to put the integument on the dorsum upon the stretch. The point of a bistoury is entered immediately above the head of the metacarpal bone,

Fig. 35.—Amputation of the Index Finger. Removing the Head of the Metacarpal Bone.

carried forwards to a point opposite the interdigital web, drawn across the side of the finger, and then carried a little way into the palm. This same process is performed upon the opposite side, the flaps are dissected down by a few touches of the knife, the extensor tendon is divided, the joint opened, and disarticulation performed. The *oval method*, which is undoubtedly the better, as it does not wound the palm, consists in entering the bistoury at the same point as in the last case, carrying it as far as the point at which the web joins the finger which is being taken off, on the operator's right hand side; then across the palmar aspect, in the line of the fold in the skin at the root of the finger, to the web on the other side. Thus far the incision may be made without taking the knife out of the wound. The oval is completed by putting the point of the knife in the end of the first incision and carrying it upwards to

the starting point, the Surgeon's hand and the handle of the knife, during the second part of the operation, being over the back of the patient's hand. The two sides of the oval should be exactly symmetrical, and the incisions from the starting point to the web should not be straight, but slightly curved in such a way that their convexities look towards the middle line of the finger which is being removed. By a few touches of the knife the oval flap is turned back: the flexor tendon is then divided and the articulation opened from the operator's right hand side: finally the finger is removed by twisting it round, while the edge of the knife is pressed against the base of the first phalanx with a slight sawing movement. As a general rule, it is better not to remove the head of the metacarpal bone with the finger, as by so doing the hand is narrowed and weakened. If the head be left, a gap of some width will remain in the situation of the finger that has been amputated: and should it be desirable for any reason to attempt to diminish this deformity, the head may be taken away in the following manner. The incision must be commenced on

Figs. 26, 27, 28. Results of Amputation above Metacarpophalangeal Articulation in Middle, Index, and Ring Fingers.

the dorsum about three-quarters of an inch above the head of the metacarpal bone, and be carried straight downwards to a point opposite the head, where a oval incision, similar to that above described, is commenced. We thus get that is known as a "racket-shaped" incision. In removing the middle and ring fingers, it will be found more convenient to take out the head of the metacarpal bone after disarticulation. This is done by cleaning the dorsal surface and sides, taking care to keep close to the bone, and not to let the edge of the knife plunge into the palm, so as to wound a digital branch at a point where it could with difficulty be secured. The bone-forceps are then closed, in a transverse direction, immediately above the head of the bone (Fig. 24). The operator then places the tip of his fore finger in the palm of the hand, so as to push the separated head slightly out of the wound, while, at the same time, he drags it downwards with his thumb placed on the cut surface of the bone. By a few touches of the point of the knife it is easily turned out, and with the slightest care all risk of wounding a digital branch is avoided. In the case of the index finger, the bone should be cut obliquely, so as to shape it to

the tapering form of the hand (Fig. 35). This may be done either with the bone-forceps or with a small saw. The saw has the advantage of making a smoother section and of leaving no splinters. If the bone be cut directly across, an ugly and inconvenient square protuberance, liable to constant injury, will be left. When, however, the patient's employment is one in which great strength and breadth of hand are required, and where appearance is of little consequence, the head of the bone should not be removed.

In amputating the little finger, with the head of the metacarpal bone, the incision must be commenced at the inner side of the hand, at a point corresponding to the middle of the shaft of the bone, and carried straight downwards to a point opposite the head, from which the oval must be begun. The flaps so formed are most conveniently held out of the way by an assistant with a pair of blunt hooks during the division of the bone. This must be sawn

Fig. 36. — Amputation of Right Thumb and Metacarpal Bone by Transfixion. Cutting the Palmar Flap.

obliquely, as in the case of the index finger. As in the index finger, the head should be left in the hand of a working man.

The after-treatment of these cases is extremely simple. The hand should be put upon a splint, the wound covered with some antiseptic dressing, and the ends of the fingers, with small pieces of lint interposed, tied together by means of a tape, care being taken, however, that they do not overlap. The shaft of the metacarpal bone that is left will gradually atrophy, and thus a very shapely hand will eventually be left (Figs. 36, 37, 38).

In disease or injury of the **Thumb** as little as possible should be removed by amputation: for, if even but a very short stump of the metacarpal bone be left, it will serve as a useful opponent for the other fingers.

Amputation of the Thumb with its Metacarpal Bone is an operation which can very rarely be required. In cases of injury the Surgeon must use all his ingenuity to save even the smallest part of the bone, or if any doubt exists as to how much can be saved, the hand should be dressed antiseptically and left to nature, a stump being fashioned later on, after the dead parts have separated. By this means more can be saved in many cases than at first

seemed possible. In cases of disease of the metacarpal bone, excision of the bone should be preferred to complete amputation. Should the operation, however, be necessary, it may be done either by the *flap* or the *oval* method. The *flap* method is thus performed: The Surgeon stands with the back of the patient's hand towards himself, the limb being midway between pronation and supination, and he holds the thumb by the ungual phalanx. In operating on the *right* side he commences the incision immediately above, and a little to the palmar aspect of the tubercle to be felt at the outer side of the base of the metacarpal bone; from this point he carries a curved incision passing immediately below the metacarpo-phalangeal articulation on the dorsal aspect to the middle of the web between the thumb and index finger. While making this incision, the operator's hands are necessarily crossed, but this causes no inconvenience if he leans slightly over the patient's hand. Still holding the thumb, the operator now supinates the hand, and passes the knife by transfixion from the lower end of the first incision, in the web, to the point at which it was commenced, taking care to keep the blade close to the palmar aspect of the metacarpal bone (Fig. 39). The palmar flap is now cut, the knife being brought out in a line exactly corresponding to the incision which has been made on the dorsal aspect. During this part of the operation the thumb must be slightly adducted, and care must be taken not to huddle over the sesamoid bones, and at the same time not to notch the flap by turning the edge of the knife too much towards the palm in trying to avoid them. The palmar flap being cut, the Surgeon gives the thumb to an assistant while he dissects back the dorsal flap by a few touches of the knife. This being accomplished, he again takes the thumb, and forcibly abducts it, while he carefully passes the knife down towards the joint, along the palmar aspect of the metacarpal bone, separating the remaining attachments of the short muscles, and finally opening the articulation from its inner and palmar aspect. During this part of the operation the knife must be kept turned towards the bone, so as to avoid wounding the radial artery as it passes between the heads of the first dorsal interosseous muscle. As soon as the joint is opened the thumb should be separated by twisting it round while the edge of the knife is sawn gently against the base of the bone. The radial artery, as it winds below the styloid process, is easily wounded at this stage of the operation, unless the knife is kept constantly in contact with the bone. In operating on the *left* side exactly the same course is followed, except that it is not necessary for the Surgeon to cross his hands, and the first incision is made from the web to the base of the bone, and the transfixion from that point to the web.

In the *oval* method of amputating, which is, as a rule, to be preferred, the incision is commenced opposite the outer tubercle at the base of the metacarpal bone, and carried along the outer border of the bone to within about half-an-inch of the hand. From this point an oval incision is carried round, passing distant over the metacarpo-phalangeal articulation, thus completing a racket-shaped incision. The flaps are then turned back, care being taken, if possible, not to open the metacarpo-phalangeal articulation, and the operation is com-

Fig. 10. Result of Amputation of Thumb and its Metacarpal Bone.

cluded in the same way as in the transfixion method. Should the metacarpophalangeal articulation be opened, the phalanges must be removed, and the head of the metacarpal bone seized in a pair of lion-forceps, after which no difficulty will be found in finishing the operation. Fig. 40 shows the hand after amputation of the thumb and its metacarpal bone.

Fig. 41. Hand after Amputation of Metacarpal Bones and First Two Fingers.

The **Metacarpal Bones**, with or without the fingers supported by them, occasionally require removal for disease or injury. For these operations, which are not of a very regular kind, it is difficult to lay down definite rules: in performing them, care should be taken to make flaps of sufficient size, and to avoid cutting into the palm if possible. It is well not to disarticulate the lower end of the bones, so as to open the wrist-joint, but rather to cut them off a little above this with

Fig. 42. Hand after removal of Metacarpal Bones and Three Fingers, leaving Thumb and Little Finger.

bone-forceps or a metacarpal saw.

In injuries from the explosion of powder-flasks or gun-barrels, when the hand is much shattered, it is of great consequence to avoid cutting up the palm to too great an extent: and it is well in these cases if possible to save a finger, which will be of more use to the patient than any artificial limb, however ingeniously constructed (Figs. 41 and 42). When

Fig. 43. Amputation of the Wrist by Tenodesis method.

only one finger is left, as the index or little finger, with the thumb, in cases of partial amputation of the hand after injury or for disease, the digit that remains not only becomes more mobile than formerly, but is increased in size and stronger, so that its utility is materially augmented. In all cases in which the extent of the injury is doubtful, the hand may be rendered

thoroughly aseptic by immersion in a bath of carbolic acid lotion (1 in 20), or some other efficient antiseptic solution, for a few minutes, and then dressed with some antiseptic dressing for a week or more, and a secondary amputation performed when the limits of the injury are clearly defined. If the prevention of decomposition is successfully accomplished, no constitutional or local trouble is caused by this mode of treatment, and the amount saved is often more than was at first expected.

The mortality after amputation of the fingers and metacarpal bones is very trifling. Should death occur after such a slight operation, it would probably be by the occurrence of some infective disease, such as erysipelas, pyæmia, or tetanus.

An excellent stump may in some cases be obtained by amputating **between the carpus and metacarpus**. All the movements of the wrist-joint remaining perfect, a very useful artificial hand can be easily applied. The covering may be taken chiefly from the dorsal or palmar surface, the latter being preferable when possible.

Amputation at the Wrist is not very often required. In performing disarticulation at this joint, its shape, with the convexity looking upwards, must be borne in mind. The operation may be performed in three ways, the chief flap being cut either from the dorsal or palmar surface or from the radial side of the hand. In the first case, it is best performed by *Teale's method* (Fig. 43). A perfectly square flap, whose four sides are each equal in length to half the circumference of the limb at the level of the wrist-joint, is raised from the back of the hand. It must consist of skin and fat only, the extensor tendons being left on the hand. A short palmar flap, also composed of skin and fat only, and equal in length to one-quarter of the dorsal flap, is next raised. The extensor tendons may now be divided at the level of the wrist, and the joint opened and disarticulated. Lastly, both flaps being held well back, the flexor tendons are smoothly divided with a single sweep of the knife. The flaps must be brought accurately together in the way described on p. 68, Fig. 26. By this method the dorsal flap is somewhat long and thin, and is consequently liable to slough unless it be very carefully raised, care being taken not to turn the edge of the skin to the flap, but to keep it constantly directed towards the parts to be removed.

In amputation by the *long palmar flap*, the operation has been performed, either by cutting the flap from within outwards after opening the wrist-joint, or by shaping the flap from the palm first and disarticulating afterwards. The former method is objectionable, as the prominence of the pisiform bone and the hook of the ulna on the inner side render its performance

Fig. 44. Amputation at the Wrist by Long Palmar Flap.

extremely difficult. In the latter method (Fig. 44) a large flap, almost square in shape, but having its angles rounded off, is marked out in the palm by an incision commencing at one styloid process and terminating at the other. The flap should extend to within one finger's breadth of the transverse fold in the palm opposite the heads of the metacarpal bones, and should include everything down to the flexor tendons. The flap is raised without difficulty till the ridge of the trapezium and the hook of the ulniform are met with. At this point great care must be taken to keep the edge of the knife turned towards the bones, while firm traction is exerted on the flap. If this be done it will usually be found that the anterior annular ligament and median nerve have been raised in the flap. When the palmar flap has been raised, a curved incision is made across the back of the wrist, with its convexity downwards, connecting the two extremities of the previous incision and marking out a flap about one inch in length. The wrist being forcibly flexed, the joint is now opened, and the ligaments divided. The hand is attached now only by the flexor tendons, which may be divided by a single sweep of the knife—the *palmar flap being carefully held out of the way*. The palmar flap will be found usually to contain the median and ulnar nerves and the superficial palmar arch, with portions of the muscles of the thumb and little finger. It is better to cut out a small piece of each nerve where it is exposed at the base of the flap, as the trunks might be a source of pain if pressed against the ends of the bones, and the branches supplying the palm of the hand arise at a higher level.

The most common error in performing this operation, and one which must be carefully guarded against, is commencing the incision for the palmar flap too much towards the palmar aspect of the wrist, instead of starting from the apices of the styloid processes. The base of the flap may thus be left very thin and narrow. In the after treatment it is better to place the stump supinated on a pillow above the patient's head, so that it shall drain better, and the flap may have less tendency to displacement.

Of these two methods amputation by the palmar flap is the better, and should always be adopted when the condition of the soft parts permits of it. If it is not possible to get sufficient covering from the palm, a good stump may sometimes be made by taking the flaps equally from the dorsal and palmar surfaces.

Amputation by the *external flap* (Dubrueil's method) is done by an incision commencing on the dorsal aspect of the wrist at the junction of the outer with the middle third and a little below the line of the articulation. The knife is carried downwards towards the cleft between the thumb and fore-finger till it reaches a point opposite the lower third of the metacarpal bone of the thumb, and then outwards across the bone to the inner side of the thenar eminence, which is followed upwards till the incision terminates on the palmar aspect, at a point exactly opposite that at which it commenced on the dorsum. The angles of the flap should be slightly rounded off in marking it out. The flap is then raised with as much of the short muscles of the thumb as possible. A second incision is then carried round the inner side of the wrist, half an inch below the styloid process of the ulna. The joint is then opened and disarticulation completed. The external flap is then brought inwards over the lower ends of the bones. This method is said to give a very good result. In all methods the end of the stump may be made more level by removing the extremities of the styloid processes with a fine saw.

In **Amputation of the Forearm** as long a stump should be left as possible, so as to give the patient more power over an artificial limb. The operation may be done by equal dorsal and palmar flaps. In a muscular limb each flap must be well rounded and equal in length to the antero-posterior diameter of the limb at the point at which the bones are sawn, as the palmar flap especially has a great tendency to retract. In amputating the right forearm, the Surgeon stands above the arm, so as to have his left hand to the dorsal flap, which he will have to raise by dissection. The hand being pronated, the incision for the dorsal flap is commenced at the palmar aspect of the radius, is carried forward for the necessary distance parallel to this bone, and then across the back of the arm in a slightly curved line, until it reaches the palmar aspect of the ulna; it then passes along this until it reaches a point opposite to that at which it has commenced, and the flap thus made is dissected back. Care must be taken that this flap is wide enough at its free extremity; it should in fact be a rectangular flap with its corners rounded off. The palmar flap is next made by transfixion (Fig. 45). As soon as it is cut, the bones are cleared by a couple of sweeps of the knife, and the interosseous membrane is divided; the bones, being of nearly equal size, are then sawn together. The vessels are cut long and will be found on each side of the palmar flap at the free end. In operating on the left side of the body, the Surgeon stands below the arm, with his left hand, as before, to the flaps, and the incision is commenced from the ulnar side. This is the easiest, but by no means the best method of amputating the forearm, for when the palmar

Fig. 45.—Amputation of the Forearm. Transfixion of the Anterior Flap.

flap is cut by transfixion considerable inconvenience is caused by the protrusion of the mass of tendons and muscles included in it. To avoid this, both flaps may be raised by dissection. It is advisable to make the dorsal flap longer than the palmar, so that the line of the cicatrix may fall well away from the ends of the bones. The operation may be thus performed (Fig. 46). The Surgeon, standing so as to take the flaps in his left hand, and holding the arm with its dorsal surface upwards, enters the knife at the palmar edge of the bone furthest from him. He then marks out a flap from the dorsal surface, equal in length to two-thirds of the antero-posterior diameter of the limb at the point where it is intended to saw the bones. The flap must be sufficiently broad, and rounded at its corners. After raising this, taking only the skin and fat, a flap similar in shape, but half the length, is raised from the palmar surface. This flap must be marked out by drawing the knife under the limb while it is still in the pronated position, but the forearm must be supinated while it is being dissected up. The knife is now firmly swept round the limb at the level of the angle of the flaps (Fig. 46), so as to divide the muscles

circularly at this point. The soft parts are now to be retracted from the bones by a process of careful dissection, or by raising the periosteum with an elevator (p. 71), for a distance equal to half the diameter of the limb at the point where the bones are to be sawn, and the bones sawn at this point. The result is, that the bones are buried in the muscles, and over all lie the light skin flaps, free from any tension or tendency to displacement. There will be a dependent opening for the exit of discharges, and, when healed, the cicatrix will be well to the palmar aspect of the bones, and consequently free from pressure. It may be found, in retracting the muscles from the bones, that the anterior interosseous artery has been cut in more than one place; this may cause some trouble in securing it. Great care should therefore be taken to avoid the accident, by keeping the edge of the knife constantly turned towards the parts to be removed, or by using the periosteal elevator. If the median and ulnar nerves are seen to be cut somewhat long, they should be pulled out with

Fig. 46. Amputation of the Forearm by Skin Flaps.

forceps, and cut short, so as to avoid if possible their implication in the cicatrix near the end of the bone.

Amputation at the Elbow-joint is not very frequently performed, as the cases in which it is practicable are not common. In all cases of disease of the elbow-joint in which excision is not advisable or has failed, the lower end of the humerus must be removed, and it is only in a few cases of sarcoma and injury that the limb can be taken off at the joint. When practicable, however, amputation at the joint should be performed. The operation is easy and the long stump left is very useful. Amputation through the elbow-joint has been done by numerous methods, of which the most common have been the long anterior flap and the circular. In the operation by the *long anterior flap* the arm is held, by the assistant, fully extended and supinated. The Surgeon stands with his left hand to the flaps. In operating on the left arm the incision is commenced about one inch below the point of the inner condyle, and carried straight down the inner side of the forearm for a distance equal to a diameter and a half of the limb at the elbow; it is then carried across the front of the forearm to the outer side and upwards to a point corresponding to that at which it commenced. On the right side the direction of the incision is reversed. The flap should be broad and nearly

rectangular in form, its angles being rounded off. The flap so marked out is then raised, including only skin and fat for a short distance, and then gradually being deepened, dividing the muscles of the forearm, the brachialis anticus and the tendon of the biceps till, at its base, it reaches the front of the joint. The knife is then swept round behind the forearm, marking out a flap about half the length of that in front. This is carefully raised from over the olecranon, care being taken not to perforate the skin. Disarticulation is then performed, the joint being opened at the radio-humeral articulation.

If the condition of the soft parts will not allow of this method, a *simple circular* amputation may be performed. It is better to make the circular sweep a little obliquely, leaving the covering slightly longer on the outer side to allow for the greater retraction caused by the supinator longus. The skin and

FIG. 47. Amputation of the Arm. Clearing the Bone.

are then turned up in the usual way, and the remaining soft parts divided circularly at the level of the articulation. Good stumps have also been made by flaps taken from the inner or outer side of the forearm, according to the circumstances of the case, by equal lateral flaps, and by various oval incisions, but the two methods above mentioned will be found most generally useful.

Amputation of the Arm may be performed by the pure circular (p. 59), by the modified circular (p. 67), or by the flap operation (p. 61). The modified circular is the best, but any method will give good results provided sufficient care be made. The covering should, as a rule, be taken equally from the two sides, as this enables the operator to saw the bone at the lowest possible point, and the utility of the stump will to a great extent depend on its length. The *flap operation* may be performed by lateral flaps made by transfixion from before backwards; the bone is then well cleared by a couple of sweeps of the knife, and sawn across. In clearing the bone, care must be taken fairly to

divide the musculo-spiral nerve by a firm sweep of the knife round the back of the bone (Fig. 47), if the amputation be performed in that part of the arm where this nerve winds round the humerus. The operation is also frequently performed by antero-posterior flaps. In this method the anterior flap includes the biceps and brachialis anticus, and the posterior contains the triceps. The brachial artery and the median nerve may be left in either flap as may seem most convenient to the operator, but care must be taken that the artery is not pierced during transfixion. The choice of the operation depends somewhat upon the condition of the limb; if it be muscular, the circular or modified circular will give the best results.

Amputation at the Shoulder-joint may be performed by the flap or the oval method. If it be required for injury the oval is preferable, but the flap method may also be employed. If it be for a tumour of the upper end of the bone the flap method by dissection will be found the best operation.

Fig. 48. — Amputation at the Shoulder-joint by Transfixion.

Hæmorrhage during the operation must be prevented by the means described at pages 47 and 50.

In operating by *transfixion*, a long narrow-bladed knife should be used. One assistant must have charge of the limb; another should raise the flap; and a third must follow the knife as it cuts behind the humerus, and grasp the inner flap with the axillary artery, so as to prevent hæmorrhage from this vessel. An assistant holding the arm away from the body so as to relax the deltoid, the knife, instead of being entered by a puncture, should make a small cut, about an inch in length, to the point at which transfixion is to be made, so as to prevent that jaggling of the integuments by the heel of the instrument which would otherwise occur. If the operation be on the *right* side, the Surgeon stands before the patient, and the point of the knife should

be entered midway between the acromion and the coracoid process (Fig. 48); and being carried directly across the joint and capsule, should pass out well behind the acromion, and about an inch below the spine of the scapula. If on the *left* side, the Surgeon stands behind, and the point of the knife must be entered well behind the acromion below the spine of the scapula, at the posterior border of the axilla, carried across to the anterior aspect of the joint, and brought out on the outer side of the coracoid process. In either case, the large flap containing the deltoid muscle must then be cut by a sweep of the knife downwards, and raised by the assistant. The heel of the knife is now to be laid on the head of the bone, the capsule of the joint cut across, and the attachments of the muscles to the tuberosities divided. In order to facilitate this part of the operation, it is generally recommended that the arm should

Fig. 49.—Amputation at the Shoulder-joint. Opening the Capsule, and making Inner Flap.

be carried forcibly inwards across the chest. This may readily be done in the dissecting-room, or in actual practice when the limb is removed for disease of the humerus, the bone being entire; but in the case of comminuted fracture high up, the lever-like action of the bone cannot be put in force, and it is sometimes no easy matter to detach the head from the glenoid cavity. In order to do this, I have found it necessary, after opening the capsule, to seize the upper fragment and draw it forcibly downwards and outwards by inserting the fingers between the head and the glenoid cavity, in order to divide the muscles inserted into it. After the head of the bone has been turned out, the knife must be passed over it and carried down for a distance of about three inches close to the bone at its inner side (Fig. 49). The Surgeon then cuts across the soft parts, so as to form the inner flap.

While he is doing this, the assistant to whom this duty is entrusted, must follow the knife with his hands, grasping firmly the whole thickness of the inner flap, so as to compress the axillary artery (Fig. 50). The Surgeon should not finish cutting the flap until the assistant tells him that he holds the vessel firmly, and then he must be careful not to injure his assistant's fingers. The artery will be found to be cut long in the middle of the inner flap, and a few smaller branches may be required to be tied at its inner angle, and in the deltoid. The stump after it is healed will present the appearance shown in Fig. 52.

Unless the deltoid is well developed and well covered by subcutaneous fat, it is usually impossible to make a flap sufficiently wide to form an efficient covering by transfixion, and it must then be raised by dissection. The

Fig. 50 - Amputation at the Shoulder-joint Holding Vessels in the Inner Flap.

line of the incision through the skin corresponds exactly with that just described. In operating on the right side, the Surgeon, standing below the shoulder, grasps the arm and carries it slightly over the trunk; he commences his incision well behind the acromion, and a short distance below the spine of the scapula, near the posterior fold of the axilla, carrying it downwards to the level of the insertion of the deltoid, and then across the outer side of the arm and upwards to a point a little external to the coracoid process. He thus follows the ordinary rule of cutting from his left hand to his right. On the left side the direction of the incision is reversed. The deltoid being dissected up, the joint is opened and the inner flap cut in the way above described. The deltoid flap may be raised by means of a short knife, should the operator prefer it; a broad bistoury is very convenient.

It must be changed for a long amputating knife after the joint is opened. This method of operating is specially adapted to cases of disease, and more particularly of tumours of the humerus, by which the soft parts are stretched and thinned.

Amputation by *antero-posterior flaps*, or Lisfranc's method, differs somewhat from the operation described above. It is thus performed :—If it is the left arm that is to be removed, the Surgeon grasps the limb as near the elbow as possible, and carries it outwards nearly to a right angle with the trunk. He then inserts the knife immediately in front of the posterior fold of the axilla, and passing it forwards so that it crosses the neck of the humerus at its posterior aspect immediately below the head, he makes the point emerge

FIG. 51. Amputation at the Shoulder by Spencer's Method.

in front of the acromion. The knife is next brought out in such a way as to cut a neatly rounded flap some four inches or more in length from the posterior aspect of the limb. The arm is then crossed over the body, the joint opened, and the operation finished in the same way as that previously described. In operating on the right side the transfixion is made from a point immediately in front of the acromion to the posterior border of the axilla. The great rapidity with which this operation can be performed caused it to be highly appreciated before the invention of chloroform. It leaves the scar, however, in a more exposed situation than when a pure deltoid flap is raised.

Amputation at the Shoulder by the Oval Method.—In cases in which, from the state of the bone, the manipulations necessary for amputation by transfixion are impossible, the method originally invented by Larrey, or some modification

of it, must be adopted. Larrey commenced his operation by a vertical incision down to the bone, about two inches in length, starting from immediately below the acromion process. He then had the wound held open by an assistant, and passed the knife round the bone in front, inclining its point downwards so as to bring it out in the axilla at its lower border close to the insertion of the pectoralis major and in front of the axillary artery: a flap was then cut by transfixion, and the pectoralis major divided. The knife was then passed behind the bone and brought out in the axilla, posterior to the vessels, and a second flap cut including the insertion of the latissimus dorsi. These flaps were turned off the humerus by a few touches of the knife, and held on one side by an assistant while the joint was opened and disarticulated. The knife was then made to glide to the axillary side of the bone, and carried downwards with its edge towards the humerus till the assistant could grasp the artery: finally, the axillary vessels and the remaining skin were divided "at the level of the inferior angles of the two flaps." The result was a somewhat irregular oval amputation. In Larrey's *Memoirs* there is a figure showing that the flaps were cut by transfixion.

Fig. 52. Stump after Amputation at the Shoulder joint.

The most important modification of this method is that of Spence, which is specially adapted for gun-shot wounds of the upper end of the humerus. It consists in making the vertical incision further forwards, commencing it just external to and below the tip of the coracoid process, as in excision of the shoulder-joint, and carrying it downwards to the level of the insertion of the deltoid. The incision ought to expose the tendon of the long head of the biceps lying parallel to it. This may be turned on one side, and the joint opened and examined: and if from the state of the parts it be still considered necessary to amputate, the operation is completed by making an oval incision through the skin from the end of the original cut, taking care not to go so deeply on the inner side as to wound the vessels. The outer flap is then dis-

sected up, so as to enable the Surgeon to get his knife internal to the head of the bone, between it and the axillary artery (Fig. 51). The assistant follows the knife with his hands, and grasps the vessels, and the operation is finished by dividing the axillary vessels, and the tissues left uncut at the inner side.

In this mode of operating much loss of blood may be saved by securing the vessels cut in the first part of the operation before opening the joint and proceeding to the division of the tissues at the inner side of the arm.

Of these operations, Spence's method is best whenever it is practicable. In tumours of the head of the bone the flap method by dissection is not suitable, as it is often necessary to remove a great part of the deltoid. In gun-shot or shell wounds the Surgeon is often obliged to do a more or less irregular operation owing to the injury to the soft parts. The transfixion methods are never to be recommended, unless for some reason rapidity of performance is desirable.

Amputation of the Arm with the Scapula and part of the Clavicle.

—There are at least fourteen cases recorded, commencing with Cheselden's in 1737, in which recovery has taken place after the whole upper limb, together with the scapula and a greater or less part of the clavicle, has been torn away. Such cases suggested the possibility of removing the same parts for tumours invading the bones in that region, and in injuries in which sufficient covering is not left for an ordinary amputation at the shoulder.

The operation has now been performed probably in nearly one hundred cases. In 1887, Paul Berger, in a monograph on the subject, collected fifty-one cases chiefly from French literature. In 1890 Chavasse published a table of 44 cases, including one of his own, in which the operation had been performed for the removal of large tumours. The immediate mortality from the operation has been about 1 in 5 for cases of disease, and 1 in 3 for injury. It is impossible to lay down definite rules for its performance, as the lines of incision must necessarily vary with the size and situation of the tumour or the condition of the soft parts in an injury.

In all cases the first step is to expose the subclavian artery and vein, and to divide them between two ligatures. This is most easily done by removal of the middle third of the clavicle, by an incision reaching from the junction of the inner and middle thirds to near the outer end. The bone should be carefully cleaned with a periosteal elevator, and divided at the outer border of the sterno-mastoid, care being taken to protect the parts beneath while sawing. The clavicle is then raised and separated from the parts under it, and again divided close to the coraco-clavicular ligaments. The subclavius muscle and the fascia under it are then carefully divided, and the great vessels exposed and divided between two ligatures, the artery being tied before the vein to prevent congestion of the limb. If time is of great importance, the vessels may simply be clamped in force-pressure forceps and tied after removal of the limb. The suprascapular artery and vein may also be divided and secured at this stage of the operation. The subsequent steps have been carried out in various ways, of which that recommended by P. Berger is probably the best. The patient is brought to the edge of the table so that the whole scapular region projects over it. The arm being abducted and the Surgeon standing between it and the body, an incision involving the skin and fat only is commenced in the middle of that already made for the removal of the portion of the clavicle and carried downwards and forwards, passing just external to the coracoid process, and then over the anterior part of the deltoid to the level of the lower border of the axilla. It is then curved inwards and backwards, so as to cross the inner side of the arm at the lower limit of the axilla, passing over the pectoralis major and latissimus close near their insertions. From the posterior border of the axilla it is continued downwards and backwards to the lower angle of the scapula. This antero-inferior flap is raised for a short distance, and the pectoralis major and minor are then divided, the latter close to its insertion. The scapula now falls away from the body, fully opening up the axilla, and the brachial plexus is now to be divided. The Surgeon now places himself outside the arm, which is carried across the chest, so as to expose the scapular region behind. The postero-superior flap is then cut by an incision starting from the outer end of that made for removal of the portion of the clavicle, and curved sharply downwards over the spine of the scapula, and continued to the point at which the anterior incision ended over the inferior angle.

divide the musculo-spiral nerve by a firm sweep of the knife round the back of the bone (Fig. 47), if the amputation be performed in that part of the arm where this nerve winds round the humerus. The operation is also frequently performed by antero-posterior flaps. In this method the anterior flap includes the biceps and brachialis anticus, and the posterior contains the triceps. The brachial artery and the median nerve may be left in either flap as may seem most convenient to the operator, but care must be taken that the artery is not pierced during transfixion. The choice of the operation depends somewhat upon the condition of the limb; if it be muscular, the circular or modified circular will give the best results.

Amputation at the Shoulder-joint may be performed by the flap or the oval method. If it be required for injury the oval is preferable, but the flap method may also be employed. If it be for a tumour of the upper end of the bone the flap method by dissection will be found the best operation.

Fig. 48. Amputation at the Shoulder joint by Transfixion.

Hæmorrhage during the operation must be prevented by the means described at pages 47 and 50.

In operating by *transfixion*, a long narrow-bladed knife should be used. One assistant must have charge of the limb; another should raise the flap; and a third must follow the knife as it cuts behind the humerus, and grasp the inner flap with the axillary artery, so as to prevent hæmorrhage from this vessel. An assistant holding the arm away from the body so as to relax the deltoid, the knife, instead of being entered by a puncture, should make a small cut, about an inch in length, to the point at which transfixion is to be made, so as to prevent that jagging of the integuments by the heel of the instrument which would otherwise occur. If the operation be on the *right* side, the Surgeon stands before the patient, and the point of the knife should

be entered midway between the acromion and the coracoid process (Fig. 48); and being carried directly across the joint and capsule, should pass out well behind the acromion, and about an inch below the spine of the scapula. If on the *left* side, the Surgeon stands behind, and the point of the knife must be entered well behind the acromion below the spine of the scapula, at the posterior border of the axilla, carried across to the anterior aspect of the joint, and brought out on the outer side of the coracoid process. In either case, the large flap containing the deltoid muscle must then be cut by a sweep of the knife downwards, and raised by the assistant. The heel of the knife is now to be laid on the head of the bone, the capsule of the joint cut across, and the attachments of the muscles to the tuberosities divided. In order to facilitate this part of the operation, it is generally recommended that the arm should

Fig. 48. Amputation at the Shoulder-joint. Opening the Capsule, and making Inner Flap.

be carried forcibly inwards across the chest. This may readily be done in the dissecting-room, or in actual practice when the limb is removed for disease of the humerus, the bone being entire; but in the case of comminuted fracture high up, the lever-like action of the bone cannot be put in force, and it is sometimes no easy matter to detach the head from the glenoid cavity. In order to do this, I have found it necessary, after opening the capsule, to seize the upper fragment and draw it forcibly downwards and outwards by inserting the fingers between the head and the glenoid cavity, in order to divide the muscles inserted into it. After the head of the bone has been turned out, the knife must be passed over it and carried down for a distance of about three inches close to the bone at its inner side (Fig. 49). The Surgeon then cuts across the soft parts, so as to form the inner flap.

While he is doing this, the assistant to whom this duty is entrusted, must follow the knife with his hands, grasping firmly the whole thickness of the inner flap, so as to compress the axillary artery (Fig. 50). The Surgeon should not finish cutting the flap until the assistant tells him that he holds the vessel firmly, and then he must be careful not to injure his assistant's fingers. The artery will be found to be cut long in the middle of the inner flap, and a few smaller branches may be required to be tied at its inner angle, and in the deltoid. The stump after it is healed will present the appearance shown in Fig. 52.

Unless the deltoid is well developed and well covered by subcutaneous fat, it is usually impossible to make a flap sufficiently wide to form an efficient covering by transfixion, and it must then be raised by dissection. The

Fig. 50 - Amputation at the Shoulder joint. Holding Vessels in the Inner Flap

line of the incision through the skin corresponds exactly with that just described. In operating on the right side, the Surgeon, standing below the shoulder, grasps the arm and carries it slightly over the trunk; he commences his incision well behind the acromion, and a short distance below the spine of the scapula, near the posterior fold of the axilla, carrying it downwards to the level of the insertion of the deltoid, and then across the outer side of the arm and upwards to a point a little external to the coracoid process. He thus follows the ordinary rule of cutting from his left hand to his right. On the left side the direction of the incision is reversed. The deltoid being dissected up, the joint is opened and the inner flap cut in the way above described. The deltoid flap may be raised by means of a short knife, should the operator prefer it; a broad bistoury is very convenient.

It must be changed for a long amputating knife after the joint is opened. This method of operating is specially adapted to cases of disease, and more particularly of tumours of the humerus, by which the soft parts are stretched and thinned.

Amputation by *antero-posterior flaps*, or Lisfranc's method, differs somewhat from the operation described above. It is thus performed :—If it is the left arm that is to be removed, the Surgeon grasps the limb as near the elbow as possible, and carries it outwards nearly to a right angle with the trunk. He then inserts the knife immediately in front of the posterior fold of the axilla, and passing it forwards so that it crosses the neck of the humerus at its posterior aspect immediately below the head, he makes the point emerge

Fig. 51.—Amputation at the Shoulder by Spence's Method

its point in front of the acromion. The knife is next brought out in such a way as to cut a neatly rounded flap some four inches or more in length from the posterior aspect of the limb. The arm is then crossed over the body, the joint opened, and the operation finished in the same way as that previously described. In operating on the right side the transfixion is made from a point immediately in front of the acromion to the posterior border of the axilla. The great rapidity with which this operation can be performed caused it to be highly appreciated before the invention of chloroform. It leaves the scar, however, in a more exposed situation than when a pure deltoid flap is raised.

Amputation at the Shoulder by the Oval Method.—In cases in which, from the state of the bone, the manipulations necessary for amputation by transfixion are impossible, the method originally invented by Larrey, or some modification

of it, must be adopted. Larrey commenced his operation by a vertical incision down to the bone, about two inches in length, starting from immediately below the acromion process. He then had the wound held open by an assistant, and passed the knife round the bone in front, inclining its point downwards so as to bring it out in the axilla at its lower border close to the insertion of the pectoralis major and in front of the axillary artery; a flap was then cut by transfixion, and the pectoralis major divided. The knife was then passed behind the bone and brought out in the axilla, posterior to the vessels, and a second flap cut including the insertion of the latissimus dorsi. These flaps were turned off the humerus by a few touches of the knife, and held on one side by an assistant while the joint was opened and disarticulated. The knife was then made to glide to the axillary side of the bone, and carried downwards with its edge towards the humerus till the assistant could grasp the artery; finally, the axillary vessels and the remaining skin were divided "at the level of the inferior angles of the two flaps." The result was a somewhat irregular oval amputation. In Larrey's *Memoirs* there is a figure showing that the flaps were cut by transfixion.

Fig. 50. Stump after Amputation at the shoulder joint.

The most important modification of this method is that of Spence, which is specially adapted for gun-shot wounds of the upper end of the humerus. It consists in making the vertical incision further forwards, commencing it just external to and below the tip of the coracoid process, as in excision of the shoulder-joint, and carrying it downwards to the level of the insertion of the deltoid. The incision ought to expose the tendon of the long head of the biceps lying parallel to it. This may be turned on one side, and the joint opened and examined; and if from the state of the parts it be still considered necessary to amputate, the operation is completed by making an oval incision through the skin from the end of the original cut, taking care not to go so deeply on the inner side as to wound the vessels. The outer flap is then dis-

sected up, so as to enable the Surgeon to get his knife internal to the head of the bone, between it and the axillary artery (Fig. 51). The assistant follows the knife with his hands, and grasps the vessels, and the operation is finished by dividing the axillary vessels, and the tissues left uncut at the inner side.

In this mode of operating much less of blood may be saved by securing the vessels cut in the first part of the operation before opening the joint and proceeding to the division of the tissues at the inner side of the arm.

Of these operations, Spence's method is best whenever it is practicable. In tumours of the head of the bone the flap method by dissection is not suitable, as it is often necessary to remove a great part of the deltoid. In gun-shot or shell wounds the Surgeon is often obliged to do a more or less irregular operation owing to the injury to the soft parts. The transfixion methods are never to be recommended, unless for some reason rapidity of performance is desirable.

Amputation of the Arm with the Scapula and part of the Clavicle.

—There are at least fourteen cases recorded, commencing with Cheselden's in 1737, in which recovery has taken place after the whole upper limb, together with the scapula and a greater or less part of the clavicle, has been torn away. Such cases suggested the possibility of removing the same parts for tumours invading the bones in that region, and in injuries in which sufficient covering is not left for an ordinary amputation at the shoulder.

The operation has now been performed probably in nearly one hundred cases. In 1887, Paul Berger, in a monograph on the subject, collected fifty-one cases chiefly from French literature. In 1890 Chavasse published a table of 44 cases, including one of his own, in which the operation had been performed for the removal of large tumours. The immediate mortality from the operation has been about 1 in 5 for cases of disease, and 1 in 3 for injury. It is impossible to lay down definite rules for its performance, as the lines of incision must necessarily vary with the size and situation of the tumour or the condition of the soft parts in an injury.

In all cases the first step is to expose the subclavian artery and vein, and to divide them between two ligatures. This is most easily done by removal of the middle third of the clavicle, by an incision reaching from the junction of the inner and middle thirds to near the outer end. The bone should be carefully cleaned with a periosteal elevator, and divided at the outer border of the sterno-mastoid, care being taken to protect the parts beneath while sawing. The clavicle is then raised and separated from the parts under it, and again divided close to the coraco-clavicular ligaments. The subclavius muscle and the fascia under it are then carefully divided, and the great vessels exposed and divided between two ligatures, the artery being tied before the vein to prevent congestion of the limb. If time is of great importance, the vessels may simply be clamped in force-pressure forceps and tied after removal of the limb. The suprascapular artery and vein may also be divided and secured at this stage of the operation. The subsequent steps have been carried out in various ways, of which that recommended by P. Berger is probably the best. The patient is brought to the edge of the table so that the whole scapular region projects over it. The arm being abducted and the Surgeon standing between it and the body, an incision involving the skin and fat only is commenced in the middle of that already made for the removal of the portion of the clavicle and carried downwards and forwards, passing just external to the coracoid process, and then over the anterior part of the deltoid to the level of the lower border of the axilla. It is then curved inwards and backwards, so as to cross the inner side of the arm at the lower limit of the axilla, passing over the pectoralis major and latissimus close near their insertions. From the posterior border of the axilla it is continued downwards and backwards to the lower angle of the scapula. This antero-inferior flap is raised for a short distance, and the pectoralis major and minor are then divided, the latter close to its insertion. The scapula now falls away from the body, fully opening up the axilla, and the brachial plexus is now to be divided. The Surgeon now places himself outside the arm, which is carried across the chest, so as to expose the scapular region behind. The postero-superior flap is then cut by an incision starting from the outer end of that made for removal of the portion of the clavicle, and curved sharply downwards over the spine of the scapula, and continued to the point at which the anterior incision ended over the inferior angle.

This flap, including skin and fat only, is raised sufficiently to expose the whole insertion of the trapezius, which must then be cut through. The limb is now allowed to fall below the table, so as to tilt forward the upper part of the scapula, and the remaining attachments are divided in the following order, the omohyoid, levator anguli scapulæ, rhomboid muscles and serratus magnus. As the levator is cut, an assistant must be prepared to seize the posterior scapular artery in force-pressure forceps. The suprascapular, if not already tied, must also be seized as soon as cut. The bleeding is comparatively slight, and the operation is by no means difficult. It is important in the first stage to remove enough of the inner part of the clavicle, otherwise there may be some difficulty in securing the vein. If there is much trouble in exposing the vessels, the upper part of the anterior incision may be made, and the pectoralis major divided to bring them more easily into view.

General Results of Amputations of the Upper Limb.—Amputations of the upper extremity are, as a rule, extremely successful. Fatal shock rarely occurs except after operations at the shoulder-joint, and consequently with good hygienic surroundings and efficient antiseptic treatment almost every uncomplicated case of amputation in the upper limb should recover. This degree of success is in fact common at the present time. Where these advantages are not to be obtained, as for example in military surgery, the average death rate has been from 20 to 34 per cent. for the arm, and from 5 to 10 per cent. for the forearm.

Amputation at the shoulder-joint for injury, although necessarily more fatal, is very successful for so severe a procedure. At University College Hospital I have done the operation six times with one fatal result. In the English army in the Crimea, the mortality was only 35 per cent., and in the American Civil War it was 39·2 per cent. When the operation is performed for disease the results are more favourable.

AMPUTATIONS OF THE FOOT.—The **Phalanges of the Toes** seldom require amputation: when they do, they may be removed in the same way as the corresponding parts of the hand.

In removing a toe at the **Metatarso-phalangeal Articulation**, the oval method should always be practised, so that the sole of the foot may not be cut into (Fig. 53). The articulation is situated about the same distance above the web as the point of the toe is below it, and the incision must therefore be commenced about half an inch above this point (Fig. 53).

In removing any of the three middle toes, those on each side must be forcibly separated, and at the same time flexed as much as possible by pieces of bandage passed round them. The toes are too short to be held aside easily by the fingers of the assistant (Fig. 53). The forcible flexion of the neighbouring toes renders the articulation more superficial, and greatly facilitates the operation.

Amputation of the Great Toe is frequently required for injury and for destruction of the metatarso-phalangeal joint by extension of inflammation into it from a suppurating bunion. In such cases the head of the metatarsal bone should never be removed if it can possibly be saved, as it forms the anterior extremity of the arch of the foot on the inner side, and its loss tends to cause the foot to turn outwards. It is a common error to leave an insufficient covering for the head of the bone, the great size of which should always be borne in mind. To avoid this the operation should be performed by the racket-shaped incision, the oval part of which should not commence till the

knife has reached the middle of the proximal phalanx, and should pass, on the inner side, over the line of the articulation between the two phalanges. This amount of covering will not be found more than sufficient. In operations for injury it is not always possible to save so much, but all should be preserved that can be.

Anatomical Guides in the Foot.—In operating on the foot beyond the removal of separate toes, certain anatomical guiding points must be kept in mind some of which are usually perceptible even in cases of disease. Opposite the ankle-joint are the two malleoli. The tips of these, it must be remembered, are not opposite each other, the external being lower down and posterior, so that when, in Syme's operation, or in Pirogoff's, the direction is given to cut from the tip of the outer malleolus to the corresponding

Fig. 52. Incision and Position of Joint in Amputation of a Toe

point on the other side, it means to a point a little behind and below the inner malleolus.

The next point of importance on the inner side is the tubercle of the scaphoid, which forms a rounded prominence about half an inch in width. Its posterior border corresponds to the articulation between the scaphoid and the head of the astragalus and its anterior to that between the scaphoid and the internal cuneiform. The internal cuneiform is about one inch in length, so that at that distance from the anterior edge of the tubercle of the scaphoid will be found the articulation between the cuneiform and the metatarsal bone of the great toe, immediately in front of which is the well marked tubercle at the base of that bone. On the outer side, below and a little in front of the internal malleolus, is the outer tubercle of the os calcis, which is often but not strictly felt. About the middle of the foot the tubercle at the base of the fifth metatarsal bone forms a very marked prominence. Midway between the base of the fifth metatarsal bone and the tip of the external malleolus is the articulation between the cuboid and the os calcis; and this point is exactly opposite the tubercle of the scaphoid on the inner side.

The **Metatarsal Bone of the Great Toe** occasionally requires removal in whole or in part. The whole of the bone may be removed by one of two methods : 1, by a racket-shaped incision ; 2, by the flap.

1. In *Amputation by the racket-shaped incision* the knife is entered on the dorsum of the foot about half an inch behind the tarsal end of the bone, and carried along the line of the bone to the level of the web between the first two toes ; it is then swept round the great toe, forming an oval incision. On the outer side the knife must cut the skin at the point at which the web joins the great toe, and on the inner side the incision must correspond exactly to that on the outer. The oval part of the incision must not be commenced too soon ; in fact, it must be nearly circular, or the covering will be found insufficient (Fig. 54). The soft parts are then dissected as cleanly as possible from the upper, inner, and under surfaces of the bones, taking care not to leave the sesamoid bones in the flap. The knife is next passed between the head of the metatarsal bone and the next toe with its edge turned towards the toe. It will now be found that the head of the bone can be separated to some extent from that of the second metatarsal bone by forcing the forefinger of the left

Fig. 54 — Amputation of the Great Toe and its Metatarsal Bone by the Racket-shaped Incision

hand between them. If it is found difficult to hold the bone with the fingers the lion forceps may be used. The knife is now passed to the outer side of the bone with its edge turned towards the tarsus, as in Fig. 54, while the metatarsal bone is forcibly pulled inwards so as to put the external ligaments of the tarso-metatarsal joint on the stretch. The knife being carried upwards with its edge closely applied to the metatarsal bone will divide the tense ligaments as soon as it touches them, and the joint will thus easily be opened. Then, by twisting the bone while the knife is closely applied to its base, the removal is completed. If the knife be not closely applied to the bone, and the ligaments put well on the stretch by forcibly pulling the toe inwards, it may enter the joint between the inner and middle cuneiform bones, and the latter bone may be removed. All danger of wounding the dorsal artery of the foot as it dips down between the two first metatarsal bones is avoided at the same time if the above directions are followed.

The operation may be greatly facilitated by commencing the incision at the heel of the foot immediately behind the tuberosity at the base of the meta-

tarsal bone, one inch in front of the tuberosity of the scaphoid. It is then carried towards the dorsum of the foot, following the line of the articulation : on reaching the dorsum it is curved sharply round into the line of the metatarsal bone, and the operation is finished as just described.

If the disease be limited to the anterior part, the shaft of the bone should be cut across with a fine saw.

This method has the advantage of leaving the sole uninjured.

2. The *flap amputation* is sufficiently explained by Fig. 55. It is far

Fig. 55. Amputation of the Great Toe and its Metatarsal Bone by an Internal Flap

inferior to that by the racket-shaped incision, as it leaves an unnecessary scar in the sole of the foot.

The **Metatarsal Bone of the Little Toe** should be removed by a racket-shaped incision, so as to avoid wounding the sole. This is best done by entering the knife just behind the tubercle of the bone, carrying it forwards

Fig. 56. Amputation of the Little Toe and its Metatarsal Bone by the Racket-shaped Incision

and inwards, in the line of its articulation with the cuboid, to the centre of the fourth digital interspace, and thence forwards to the web of the toe ; the knife is next carried round the plantar surface of this, the incision being continued obliquely into that which has been made on the dorsum of the foot (Fig. 56). The small flap thus formed is well dissected down, the

knife passed round the under surface of the bone, and the joint opened by the toe being forcibly drawn outwards, and its ligamentous connections divided.

The middle metatarsal bones, when diseased, do not admit of separate removal so as to leave a useful foot.

Amputation of the Metatarsus.—When the metatarsus and anterior part of the foot are diseased or injured so as to require removal, the amputation may be effected by one of two methods; viz., 1. By making a long flap from the sole and a short flap from the dorsum, and then sawing across the metatarsus as a whole above the seat of injury or disease; or, 2. By disarticulating the metatarsus from the tarsus.

The first operation—that of sawing through the metatarsus—is sometimes called Lisfranc's; but in reality it was practised and described by Hey long before Lisfranc's time. By "Hey's Amputation" is usually meant the disarticulation of the metatarsus from the tarsus, and the formation of a flap from the anterior part of the sole of the foot. But by reference to Hey's works ("Practical Observations," London, 1814, pp. 550, 553 and 554), it will be found that he describes three different operations, only one of which agrees with this. Thus it would appear that in his first case Hey *sawed across* the metatarsal bones after having made the flap. In the second case, he *dissected out* all the metatarsal bones, and then made a flap from the sole; and in the third, he first made the sole-flap, and then, having *dissected out* the four smaller metatarsal bones, *sawed across* the internal cuneiform; thus combining the two methods of cutting and sawing. In order to avoid any possibility of error, it is better to discard the terms Hey's and Lisfranc's operation, and to describe these proceedings as "amputation through the metatarsus," and the "tarso-metatarsal amputation."

The *whole of the Metatarsus* may be removed from the tarsus by making a curved incision in the sole of the foot, reaching to the roots of the toes, one horn of which commences at the tubercle of the fifth metatarsal bone, whilst the other terminates at that of the first, or one inch in front of the tubercle of the scaphoid. The flap thus marked out is carefully raised, taking skin and fat only for the first inch, and after that all the soft parts down to the bone. On the left side the direction of the incision is reversed. A small flap is then made on the dorsum of the foot and the articulations are exposed. These must then be opened with some care, as they are very irregular (Fig. 57); the second metatarsal bone being sunk between the inner and outer cuneiform bones, and the articulation of the fifth with the cuboid being very oblique. The line of the articulation is best found by forcing downwards the anterior part of the foot, while the point of the knife is drawn across the line of the joints. As the articulations are touched they gape slightly, but they are prevented from opening fully by the very strong interosseous ligament which passes between the outer side of the internal cuneiform and the base of the second metatarsal bone. This can be divided only by forcing the knife upwards between the two bones, taking care while so doing not to wound the base of the sole flap with the point. As soon as this ligament is divided, the whole line of joints readily breaks open, and disarticulation is performed without farther difficulty. This operation is seldom acted, disease being rarely limited to the metatarsal bones, but usually affecting the joints as well. Disarticulation from the tarsus is, moreover,

troublesome, on account of the irregularity of the line of articulation ; hence it is better to saw through the metatarsus just in front of the tarsal articulations. A combination of these two procedures may sometimes be advantageously adopted ; as by disarticulation of the first metatarsal bone, and sawing the rest anterior to their articulations. In many cases the best result will be

Fig. 57 - H. Line of Hey's, or Tarsometatarsal Amputation. A Line of Chopart's, or Metatarsal Amputation.

Fig. 58 - Chopart's Operation. Flap formed before Disarticulation.

obtained by simply dissecting back the sole of the foot, clearing the bones, and sawing them across at a convenient line.

Amputation through the Tarsus may conveniently be performed by Chopart's, or the medio-tarsal, operation, which consists in disarticulation in the line between the os calcis and astragalus behind, and the cuboid and scaphoid in front (Fig. 57). This operation may be performed in two ways, either by first making the flap from the sole of the foot, and then disarticulating (Fig. 58) ; or, the joints having been cut through from the dorsum, the flap may afterwards be made (Fig. 60). In the latter plan, a smoother end will be obtained by transfixing the flap as in Figure 60, and cutting it in two parts from the middle. I prefer the first plan, as it enables the Surgeon to make a more correctly fashioned flap.

In operating on the *left* foot, the knife, a stout bistoury, should be entered immediately behind the tubercle of the scaphoid, and carried forwards to the

Fig. 58. A. Line of Incision for Amputation of Great Toe and Metatarsal Bone. B. Line for Chopart's Amputation. C. Line for Excision of the Os Calcis.

head of the metatarsal bone of the great toe, then across the sole, and down the outer side of the foot, as far as midway between the tip of the external malleolus and the base of the fifth metatarsal bone. The two guiding points are exactly opposite each other, and if one is concealed by the swelling of the foot, the other can usually be found. (On the *right* foot the line of incision is reversed, being commenced on the outer side and finished on the inner (Fig. 59, n). The flap should be made long, especially at the inner side, but well rounded at the angles. For the first inch it should consist of skin and fat only, the flexor tendons of the toes being left undivided; from this point to its base the whole of the soft parts must be dissected out from the concavity under the metatarsal bones. The sole flap having been raised, a convex incision is made over the dorsum, marking out a short flap about one inch in length, which must be raised by dissection, including all the soft parts except the tendons. The parts are well retracted, the extensor tendons divided, and the articu-

lations opened by the Surgeon bearing firmly upon the anterior part of the foot, and lightly touching the ligamentous structures with the point of his bistoury. In this stage of the operation, care must be taken that the edge

Fig. 60. Chopart's Amputation. The Flap being cut after Disarticulation.

of the bistoury be not inclined too much backwards, lest it slip over the astragalus and open the ankle-joint; or too far forwards, lest it pass anterior to the scaphoid—between it and the cuneiform bones. In more than one

instance, I have found firm osseous ankylosis in the articulations, requiring the use of the saw for the separation of the anterior part of the foot. When this complication occurs, the tarsus should be treated as a whole, and sawn through, irrespective of articulations, behind the limits of the disease. The result of this operation is extremely favourable, the patient, by the aid of a properly constructed boot, being able to walk, and even dance, with very little appearance of lameness. In some cases the heel is drawn up by the muscles of the calf, and the end of the stump is made to point down in such a way that the patient is rendered lame by walking on the anterior sharp edge of the calcaneum. Verneuil states that he has observed, in a number of cases, that the heel is drawn up only in amputations for disease, and that it occurs really before the operation and not after. He has never noticed it in a primary amputation. This condition is best removed by division of the tendo Achillis.

Tripier's Modification of Chopart's Amputation.—In order to prevent the tilting downwards of the extremity of the stump Tripier has suggested sawing off the under part of the os calcis so as to present a flat surface for the patient to bear upon. In his operation the incision is commenced at the outer border of the tendo Achillis at the level of the tip of the external malleolus and carried downwards and forwards in a curve with the convexity downwards, passing about a finger's breadth above the base of the metatarsal bone of the fifth toe and ending at the inner side of the tendon of the extensor proprius hallucis over the articulation between the astragalus and the scaphoid. From this point the plantar incision is commenced, passing at first downwards over the scaphoid and internal cuneiform bones to the level of the articulation between that bone and the first metatarsal, then downwards and inwards in a curve to the sole of the foot and across to the base of the fifth metatarsal bone, from which it is carried upwards to join the first incision. (Fig. 63, r.) These incisions must extend to the bones. The flaps are then raised so as to expose the medio-tarsal joint at which disarticulation is performed. The soft parts are then raised from the under surface and sides of the os calcis with a periosteal elevator until a long narrow saw can be applied to the inner side of the bone immediately below the sustentaculum tali. (Fig. 62, r.) The lower and posterior part of the os calcis is then sawn off by a transverse cut so as to leave a flat level surface upon which the patient may rest. The angle left between the articular surface of the cuboid and the saw cut may be rounded off.

The operations just described are adapted to cases of disease, as it is important not to leave a part of the affected bones behind, and their removal is made more certain by operating through the lines of the articulations. In amputations for injury, however, it has been recommended by Mayor, of Lausanne, and others, to treat the foot as a whole, ignoring articulations. On this plan, a sufficient covering is turned up, encroaching on the foot as little as the nature of the injury will allow. When sufficient covering has been obtained, the saw is applied to the tarsus or metatarsus, as the case may be, saving as much of the foot as possible. There is no doubt that excellent results are obtained by this method, every half-inch of the foot that can be saved adding to its utility.

Sometimes the exact limits of the injury are difficult to ascertain with accuracy immediately after the accident. In such cases any loose or crushed fragments may be removed, and the foot placed for a quarter of an hour in a

bath of 1 in 20 carbolic acid lotion. It may then be dressed antiseptically, and the amputation deferred till the exact limits of the injury can be clearly ascertained. This line of practice was followed in two cases in University College Hospital. In one, the foot, which seemed at first hopelessly crushed, completely recovered; in the other it also recovered, with the exception of the great toe, which was amputated at the end of the second week.

The Subastragalar Amputation is seldom practised in this country, but seems to be more commonly adopted in France. In it the whole foot is removed except the astragalus. Several methods have been recommended for amputation in this situation, of which the following recommended by Nelaton is perhaps the simplest. In operating on the right foot, the incision is commenced about three-quarters of an inch below the external malleolus, in front of the insertion of the tendo Achillis, and carried, at first forwards

Fig. 61.—Subastragalar Amputation. *a*, Tendo Achillis; *b*, Interosseous Ligament.

for a short distance, and then in a curved direction downwards to the sole of the foot, so as to pass just behind the base of the fifth metatarsal bone. It then crosses the sole, and is brought up to the inner side of the foot, terminating about half an inch anterior to the tubercle of the scaphoid. The extremities of this line are then joined by a curved incision across the dorsum of the foot, reaching downwards to the lower edge of the scaphoid. The soft parts are then raised from the bone on the outer side, sufficiently to reach the tendo Achillis, which is to be divided (Fig. 61, *a*). On pushing the finger into the wound the upper surface of the os calcis, and the line of its articulation with the astragalus can now be felt. The point of the knife is next to be thrust into the articulation, and the interosseous ligament divided (Fig. 61, *b*), while the foot is wrenched forcibly inwards. Care must be taken not to injure the ligaments between the os calcis and the cuboid, or all power over the former bone would be lost. When the interosseous ligament

is divided, the astragalo-scaphoid articulation is to be opened, and finally, by twisting the foot so as to put the parts on the stretch, the soft parts at the inner side and the remainder of the heel flap are to be separated from the calclea and the foot removed. In this amputation a good, long, useful stump results, which is said to possess greater elasticity from preserving the

Fig. 61.—S. Syme's Operation. T. Line of division of Os Calcis in Tripler's Operation.

ankle-joint; but the cases suited to it must be few, as it does not often happen that disease affects the calcaneum and the anterior range of tarsal bones, without the astragalus also being involved.

Disarticulation of the Foot at the Ankle-joint was first reduced by Syme to a regular operation. By its performance amputation of the leg may

Fig. 62.—T. Line of Incision for Tripler's Operation. S. Line of Incision for Syme's Operation. P. Line of Incision for Pirogoff's Operation.

then be avoided, the patient being left with an exceedingly useful stump, which, as its covering is taken from the heel, constitutes an excellent basis of support. In describing the operation on the right foot Syme's words as to the direction of the incision are: "The foot being held at a right angle to the leg, the point of the knife is introduced immediately below the malleolar projection of the fibula, rather nearer its posterior than anterior edge, and then

carried across the bone, slightly inclining backwards, to the inner side of the ankle, where it terminates at the point *exactly opposite* its commencement" (that is, a little below and behind the internal malleolus). On the left side the direction of the incision is reversed. "The extremities of the incision thus formed are then joined by another passing in front of the joint. The operator next proceeds to detach the flap from the bone" (Fig. 64). The object of carrying the incision so far back is, that the dissection of the flap may commence from the most prominent point of the plantar surface of the os calcis, that is to say, from the anterior part of the two tubercles of that bone. Every eighth of an inch in front of this point increases the difficulty of raising the flap. When the heel flap is turned back, the ankle-joint must

Fig. 64. Syme's Amputation of the Foot.
Clearing the Os Calcis.

Fig. 65.—Syme's Amputation of the Foot.
Anterior Incision and Disarticulation.

be opened in front by cutting firmly across the line of the articulation, which is about half an inch above the tip of the inner malleolus, while the foot is forcibly extended. As soon as the joint opens sufficiently, the lateral ligaments are to be divided by cutting downwards between the malleoli and the lateral surfaces of the astragalus. The tendo Achillis is divided by pressing the foot forcibly downwards and cutting from before backwards, unless it has already been cut in turning back the heel flap. By twisting and dissecting at the same time the os calcis is completely separated from its soft attachments, and the foot removed (Fig. 65). The soft parts are then turned up from the lower ends of the tibia and fibula, the knife being kept close to the bones so as not to wound the vessels that lie immediately behind each malleolus. The whole of the parts of the tibia and fibula which enter into the ankle-joint are then sawn off, the arteries tied and the flap brought up. Care must be taken

that no button-hole apertures be made through the heel flap. This may easily be avoided when the soft structures are thickened and infiltrated by inflammatory products: but, if the operation be required for injury, great care is required in digging out the heel, the integuments of the posterior part of the *os calcis* being very thin and adherent to the bone. It is also of importance that the first incision should be (Figs. 62, 63) distinctly inclined backwards towards the heel, and not forwards into the sole of the foot. Unless this be done, a large cup-shaped flap will be left, in which blood and discharges may accumulate, and retard healing. If union takes place by the second intention, bagging of discharges in the flap must be prevented by uniform elastic pressure and bandaging. The tendency to sloughing occurs chiefly in primary amputations. It has frequently been stated that it is necessary, in order to ensure the vitality of the flap, to cut the posterior tibial artery "as long as possible," and it is this as much as anything that has led to the production of the large cup-shaped flaps which are so difficult to dissect off the *os calcis*, and which so often slough. An examination of the vascular

Fig. 66. Line of Incision for Pirogoff's Operation—modified by Oblique Section of the *Os Calcis*.

supply will show that the posterior tibial artery may be cut close to the base of the flap, without interfering with the chief vessels supplying it. The distribution of vessels to the part is as follows. On the outer side, the peroneal artery, after giving off the anterior peroneal, is continued along the posterior aspect of the tibia to the outer side of the *os calcis*. On the inner side a branch of considerable size arises from the posterior tibial artery, about one inch above the ankle-joint, and passes down to the inner side of the *os calcis*, running behind the inner malleolus and accompanying the cutaneous nerve from the posterior tibial to the heel. There is thus a trunk on each side running down to the heel behind the malleolus, and these two communicate freely with each other, superficially over the cutaneous surface of the *tendo Achillis*, and deeply between the tendon and the ankle-joint: and they terminate by anastomosing by long loops on the under surface of the posterior part of the *os calcis*. It is upon these anastomosing loops that the vitality of the flap depends: and as they lie much nearer the bone than the skin it is evident that, unless the knife be kept hard upon the bone during

the whole dissection of the flap, they will be divided in large numbers, greatly endangering its vitality. In the operation as performed by Syme, the dissection of the flap is commenced from the most prominent part of the tubercles of the os calcis, and the knife can be kept in constant contact with the bone with the greatest ease. If, on the contrary, the incision extend far into the sole of the foot in front of the tubercles of the os calcis, it is almost impossible to dissect the flap back without the point of the knife being directed into its under surface and the vascular loops being divided.

This operation is a most useful one in all cases requiring removal of the

Fig. 67. Pirogoff's Operation. Sawing the Os Calcis obliquely downwards and forwards.

whole foot. The mortality attending it is but small. The stump that is left admits of the whole weight of the body being borne upon it.

Various modifications of Syme's amputation may at times be practised with advantage, when the soft parts covering the heel are not in a condition to form a good basis of support. In these circumstances, the flaps may be fashioned on the side instead of from behind: and in this way I have more than once formed an excellent covering. These lateral flaps should not, however, be made in any case that admits of disarticulation at the ankle in the ordinary way, as they never afford so good a basis of support as the integuments of the heel.

Pirogoff's Amputation is characterised by the preservation of the posterior portion of the os calcis. In operating on the right side, an incision is carried across the sole of the foot from the tip of the external malleolus to the corre-

standing point on the other side ; when operating on the left foot the direction of the incision is reversed. This incision should not be made directly transverse to the foot, but should incline forwards obliquely at an angle of about 45° to the line of the leg, the foot being held at right angles to the limb, so that the centre of the incision in the sole may (Fig. 66) reach a little beyond the anterior extremity of the os calcis. The knife should then be sunk in down to the bones, care being taken in crossing the sole of the foot that the blade is not turned at right angles to the sole, but is slanted obliquely backwards in the line of the incision from the malleolus. The ankle joint is then opened, as in Syme's operation, by an incision across the front. The foot is now forcibly extended to the greatest possible extent, a common amputation-saw or a jaw-saw is applied immediately behind the astragalus, and the bone cut obliquely downwards and forwards in the line of the incision in the soft parts, so that the saw should come out immediately behind the articulation of the os calcis with the cuboid (Fig. 67) ; the malleoli are then removed, together with a thin slice of the tibia, including the whole articular cartilage (Fig. 68).

Fig. 68.—Pirogoff's Amputation. Appearance of Parts after Removal of Malleoli.

Fig. 69.—Stump after Pirogoff's Amputation.

The opposed osseous surfaces must then be accurately adjusted, and the limb laid on the outer side, with the knee placed so as to take off the tension of the tendo Achillis. The advantages of the long oblique section of the os calcis over the shorter almost vertical cut originally made by Pirogoff are, as Busk pointed out, that a larger surface of the os calcis is brought into contact with the sawn end of the bones of the leg ; that the piece of bone left in the flap does not require to be tilted so much on its own axis, and that consequently the tendo Achillis is not put so much on the stretch ; and that the thick skin of the plantar surface of the heel still serves as the basis of support instead of the thin skin of the back of the heel, which is turned downwards in the other method. The alleged advantages of this operation over Syme's amputation consist in the stump being longer, to the extent of the thickness of the portion of the os calcis left in it, and being better adapted for pressure (Fig. 69) :

and in the diminished risk of sloughing of the flap, as its vascular communications are not much disturbed. These advantages are not, however, always real, and are in some degree counterbalanced by the liability to recurrence of the disease for which the operation may have been performed, in the portion of the os calcis left in the flap. When it is practised for injury, however, this objection does not hold good.

After either Syme's or Pirogoff's operation, patients can run; which they cannot do after amputation of the leg in any part.

In cases of caries of the tarsus requiring amputation, it occasionally happens that the Surgeon cannot determine with certainty whether the morbid condition is limited to the anterior range of tarsal bones, or extends so far backwards as seriously to implicate the astragalus and calcaneum; and he is consequently unable to decide whether the condition of the foot admits of removal by Chopart's operation, or requires disarticulation at the ankle-joint. In these circumstances all doubt will be cleared away by making an incision across the dorsum of the foot in the line of the astragalo-scaphoid and calcaneo-cuboid articulations; these are then opened, and the state of the bones is examined. If the astragalus and calcaneum be sound, or but slightly diseased on their anterior aspect, Chopart's operation may be done, and any carious bone left behind gouged away. If, on the contrary, these bones be found to be deeply implicated, the flap may be dissected back for about an inch, and disarticulation at the ankle-joint proceeded with.

Results.—The amputation of a toe, of a metatarsal bone, or even of a portion of the metatarsus, is but very seldom attended with fatal consequences. Should death occur, it must be the result of an accidental attack of tetanus, erysipelas, or pyæmia. Disarticulation at the ankle-joint, though necessarily somewhat more dangerous, is yet one of the most successful operations in Surgery, the mortality attending it being but very small.

The statistics of uncomplicated cases from the practice of Socin, Volkmann, and Max Schedo, under antiseptic treatment, show 65 cases, with 2 deaths, 1 in a woman, aged 77, and 1 re-amputation. Those of Bruns, Bardeleben and Billroth, in the pre-antiseptic period, show 39 cases, with 10 deaths, 8 of which were from pyæmia. The highest mortality was from Pirogoff's operation, of which there were 13 cases, with 5 deaths, 4 from pyæmia and 1 from erysipelas.

AMPUTATION OF THE LEG.—The selection of the line of amputation must depend upon the extent of the disease or injury, but, whenever practicable, the operation should be performed low down; the mortality diminishing in proportion as the limb is removed near to the ankle. Surgeons used formerly, even where the disease or injury was limited to the foot, to amputate immediately below the knee, or, as it was said, "at the seat of election," in all those cases in which the patient would be obliged to wear a common wooden pin, the long leg-stump being highly inconvenient when the patient rested on his bent knee; whereas, in those individuals who could afford the expense of a well-constructed artificial limb, the amputation, when practicable, was done in the lower part of the leg. But this difficulty has been removed by the introduction of a short wooden pin, in the socket of which the stump may be fixed in the extended position; and amputation in all admissible cases should consequently, even amongst the poorer classes, be done as low down as possible.

The number of arteries divided will depend upon the situation of the

amputation. Holden lays down as a general rule that in amputations one inch below the head of the fibula, only one main artery—the popliteal—is divided. At two inches two arteries—the anterior and posterior tibial—and at three inches three, are cut, the peroneal being divided in addition to the two tibials.

Flap Amputation of the Leg by Transfixion, which was at one time the operation usually performed in this country, is performed in the following way. The Surgeon stands with his left hand to the part to be removed, while the assistant, whose duty it is to retract the flaps, takes his stand opposite to the Surgeon. In the *right* limb, the point of the knife is entered at the posterior edge of the tibia, carried downwards for a distance of one inch and a half to two inches, then across the front of the leg to the posterior border of the

Fig. 70. Amputation of the Right Leg. Transfixion of the Posterior Flap.

fibula, up which the incision is made to extend to a corresponding distance. In the *left* leg the same incision commences on the fibular side of the limb, and terminates on the tibial. The flap thus formed, which should be broad and well rounded, is next dissected up by a few touches of the point of the knife, and transfixion of the limb is made by passing the blade across behind the bones, from one angle of the incision to the other (Fig. 70), taking care not to pass the knife between the bones instead of behind them. The posterior flap is then formed by cutting obliquely downwards and backwards: it should be about three inches long. The bones are next cleared by a double sweep of the knife, and the interosseous soft parts divided by carrying the instrument in a figure-of-8 way between and round the bones. In doing this, special care must be taken not to direct the edge upwards, so as to split either of the tibial arteries, more particularly the anterior: for, as the vessel retracts above

the membrane, its ligature is no easy matter. If the amputation be performed just below the knee, it is possible that the popliteal trunk may be divided above its bifurcation, and thus only one artery may require ligature. In

Fig. 71.—Amputation of the Leg by the Long Posterior Flap. Sawing the Bones.

sawing the bones the fibula must be divided first, as otherwise it may be fractured above the line of amputation. It is better to commence sawing on the tibia till the saw has entered a short distance, and then by sinking or

Fig. 72.—Amputation of the Leg by Teale's Method.

raising the hand, according to the side on which the operation is being performed, the saw is brought to bear on the fibula, which is completely divided before the tibia is finished (Fig. 71). After the removal of the limb, the sharp anterior edge of the tibia must be sliced off obliquely, to lessen the risk of sloughing of the flap from pressure upon a sharp ridge of bone.

If the limb be very muscular, a large mass of the muscles of the calf will be left in the posterior flap; this will be a good deal in the way during treatment, as its weight tends to displace the flap. In some cases I have advantageously removed the greater part of the muscular mass thus left, leaving little more than a skin flap. The inconveniences arising from the long posterior flap are, however, so great that it is better as a rule to adopt some other method of amputation.

In the *lower third of the leg*, **Teale's operation** (Fig. 72) can be performed according to the rules laid down on p. 68. The size of the wound may, however, be diminished by making part of the covering by retracting the soft parts from the bones, instead of entirely by flaps as in Teale's method. In this modified plan of operating an anterior flap is made equal in length to the diameter of the limb at the point at which the bones are to be sawn; it should be almost rectangular in shape, merely having the angles rounded off. A very short posterior flap may be cut to meet this by carrying the knife behind the limb somewhat obliquely from one end of the first incision to the other. The soft parts are then retracted by the knife, or better by the periosteal elevator, thus saving the periosteum, and the bone is sawn an inch or more above the angle of the flaps. As in Teale's method, the flaps should contain all that can be taken from the bones, for in this situation they are somewhat liable to slough. The bones in this part of the leg occupy almost the whole thickness of the limb, and it is necessary, therefore, to make the anterior flap equal to the diameter in length, so that the scar may be behind them. If there is any difficulty in retracting the soft parts, Lister recommends that the incision should be carried, on the fibular side, as high as the point at which the bones are to be sawn, as this greatly facilitates their separation. In order to avoid unnecessary wounding of the anterior tibial artery, Teale recommends that the soft parts should be raised from the interosseous membrane with the thumb-nail.

In the *middle and upper thirds of the leg*, the bones lie more towards the anterior aspect of the limb, and consequently it is not necessary to cut so long an anterior flap in order that the cicatrix may be placed behind them. In these situations the anterior flap may be made equal in length to two-thirds of the diameter of the limb, and the posterior flap one-half the length of the anterior, the rest of the covering being made by retraction of the soft parts from the bones. The anterior flap should consist, at its lower edge, of skin and fat only, but it should be gradually deepened as it is raised, till at its base it contains almost all the muscle that can be obtained from the front of the limb (Fig. 73). In dissecting up the posterior flap, which should contain only skin and fat, the limb should be raised so that the Surgeon can more conveniently see what he is doing. Both flaps being held well out of the way, the muscles are next divided circularly, and the soft parts raised from the bones for a distance equal to at least one-third of the diameter of the limb. In doing this, care must be taken not again to wound the anterior tibial artery. Finally, the bones are sawn as high as possible. The sharp point of the tibia must be rounded off. In doing this, if the retraction of the soft parts have not already been done with a periosteal elevator, it is well carefully to raise the periosteum before applying the saw, as by so doing the tendency to necrosis is somewhat diminished, the periosteum not being torn away to a higher point than that at which the bone is actually sawn. In primary amputations the soft parts can

always be retracted without difficulty. In secondary amputations, when the parts are swollen, it may be necessary to make an incision upwards on one or both sides from the angle of union of the flaps towards the point at which the bones are to be sawn.

If from any cause there should not be sufficient skin available to form the long anterior flap, the **circular operation**, or the modification of it recommended by Liston, as described on p. 67, may be employed instead (see Fig. 24, p. 68). All these operations have the great advantage of getting rid of the heavy mass of the muscles of the calf, and that by the long anterior flap

Fig. 73. - Amputation of the Leg by Long Anterior and Short Posterior Skin Flaps, with Circular Division of the Muscles.

secures in addition that the cicatrix shall be well behind the cut ends of the bones, and that there shall be a dependent opening for the exit of the discharges. The long anterior flap tends to keep itself in position by its own weight, and no strapping is required as in the amputation by the long posterior flap, and thus a great source of pain to the patient and of disturbance to the stump is avoided. There is also much less tendency to protrusion of the bone, as the weight of the flap is hardly sufficient to cause ulceration, if the end of the tibia has been carefully rounded.

Treves has obtained good results by the use of the **large external flap** recommended by Farabeuf for amputation at the seat of election. The flap is equal in length to the diameter of the limb at the point where the bones are

divided. The incision which marks out the flap begins in front at this same level, and ends behind at a point $1\frac{1}{2}$ inch lower, whence an incision passes straight round the inner side of the limb. In dissecting up the flap the muscles must be cut through obliquely, and care taken that the anterior tibial artery is left uninjured on the deep surface of the flap.

Results.—The mortality after amputation of the leg was formerly very high, varying generally in different hospital reports from 50 to 80 per cent., the chief causes of death being pyæmia, gangrene of the stump and exhaustion. The death-rate was higher in secondary than in primary operations, and fell to 23.5 per cent. in cases in which the operation was performed for disease. So far as situation is concerned, as a general rule, the nearer the knee the greater the danger. The high death-rate formerly prevailing has now been much reduced. In the statistics published by Max Schede (p. 83), amongst the uncomplicated cases treated antiseptically, are 19 amputations for injury and 50 for disease, with only 1 death, and that was from erysipelas, in a patient who had previously suffered more than once from the disease. Amongst the uncomplicated cases treated by Bardeleben, Billroth, and Bruns, without antiseptics, were 28 for injury, with 15 deaths, and 87 for disease, with 25 deaths; 29 of the deaths were from pyæmia and 7 from septicæmia.

AMPUTATION THROUGH THE KNEE-JOINT, originally recommended in the sixteenth century by Hoin, and reintroduced by Velpeau, Markoe, and Brinton, has long found favour in this country and in America.

Amputation through the knee-joint may be performed in three different ways: 1, with a long anterior and a short posterior flap: 2, with lateral flaps; 3, with a long posterior and a short anterior flap.

1. The operation by means of a **Long Anterior and Short Posterior Flap** is thus performed. A long square flap, rounded at the corners, is made by entering the point of a short broad-bladed amputating-knife towards the posterior part of one condyle, carrying the incision downwards in a straight line for four or five inches, then across the limb, and cutting upwards to a point on the opposite side corresponding to that of entry. The integuments and the patella are then dissected from the front of the joint (Fig. 74). The articulation is thus opened; the ligaments are then successively divided, the limb being forcibly bent; and a posterior flap is formed by cutting from behind forwards, or by dissecting down behind the bones and then cutting backwards. The flap should be about $2\frac{1}{2}$ to 3 inches long. If made shorter than this, it is apt to retract up the back of the thigh. Indeed, in all cases there is a great tendency to this, even when the flap is of the length above given. The popliteal artery is divided, and, with the exception of the articular vessels, is the only one requiring ligature.

The management of the patella is an important question; some Surgeons insist on its removal and others its preservation. I think that it is decidedly better to leave it, as it forms an important protection to the end of the stump. If it be removed, the flap becomes so thinned as to incur danger of gangrene. I have practised the operation both ways, and have from my experience found it most advantageous to leave the patella. There is only one objection to this; and that is the chance of the patella being drawn up, as occasionally happens, upon the anterior part of the thigh. This is best prevented by cutting across the tendinous insertion of the quadriceps extensor during the operation.

The cartilage on the femur should be left untouched, as thus the cancellous structure is not opened, and one predisposing cause of pyæmia is avoided. The operation is not adapted to cases in which the joint is diseased; in them it is better to amputate through the condyles.

In the after-treatment great trouble may arise from accumulation of the discharges in the synovial pouches.

This can be prevented only by proper drainage and pressure. Before closing the wound, two long tubes must be put in, in such a way that their deep extremities lie in the extreme upper parts of the synovial pouches, and their lower ends at the angles of the wound. These tubes should not be touched till the third day; after that they may be drawn out half an inch or more at each dressing, and the projecting piece cut off. They must on no account be completely removed in order to shorten them, as it would be impossible to replace them. Should pus form in the synovial pouches from failure of the drainage, it will be recognised by the swelling, redness and pain, with fluctuation. A free incision must be made into it as soon as the condition is recognised, or the pus may burst through the limits of the synovial pouch, and burrow up the thigh beneath the vasti. These precautions for drainage are necessary in all amputations in which the synovial pouches are opened.

2. Stephen Smith disarticulates at the knee by **Lateral Flaps** in the following way: The incision is commenced in the middle line in front, about an inch below the tubercle of the tibia, and is carried downwards and backwards over

Fig. 74.—Amputation through the knee by Long Anterior Flap.

the side of the leg, until it reaches the under surface, where it is directed upwards and towards the median line. When that point is reached, it is carried directly upwards to the centre of the popliteal space. A second incision begins at the same point as the first, and pursues a similar direction on the opposite side of the limb, the two incisions meeting in the median line behind. The flaps are next raised, and the soft parts dissected up circularly until the joint is opened, and the leg then removed. The inner flap should be rather the larger, because of the greater size of the inner condyle; the patella

is left. After this amputation, the stump presents the appearance represented in Fig. 75. The operation, which is in reality rather a modified circular method than a true amputation by lateral flaps, gives the most excellent results. Bryant, who has recorded twenty cases, speaks highly of it, and recommends that in raising the flaps the knife should be kept close to the head of the tibia so as to divide the coronary ligaments, and thus leave the semilunar cartilages closely encircling the condyles of the femur. "By this means the upper part of the synovial capsule is held down firmly to the condyles of the femur, and thus all the soft parts are kept well in place." This mode of operating was first described in 1872 by Brinton.

3. The operation with the **Long Posterior and Short Anterior Flap** has the great disadvantage that the posterior flap has an almost uncontrollable

Fig. 75.—Amputation at the Knee by Lateral Flap.

tendency to retract, and it should never be undertaken when the covering can be obtained more extensively or entirely from the front. It may be readily returned in the following way. An incision is made directly across the stump, just below the patella. The skin-flap thus formed is dissected back, and, the joint being opened above the patella, and the ligaments severed by a few touches of the knife, a long posterior flap is cut from the upper part of the calf of the leg, by passing the knife behind the tibia, and carrying it downwards for a suitable distance.

AMPUTATION THROUGH THE CONDYLES may be done in three different ways: 1, with a long anterior flap, including the patella or not; 2, by a modified circular method; 3, with a long posterior flap.

4. Garden, of Worcester, was the first to employ the method of amputation by the **long anterior flap** in this situation. He took away the patella and made no posterior flap; but subsequent operators have found that without a

and in the diminished risk of sloughing of the flap, as its vascular communications are not much disturbed. These advantages are not, however, always real, and are in some degree counterbalanced by the liability to recurrence of the disease for which the operation may have been performed, in the portion of the os calcis left in the flap. When it is practised for injury, however, this objection does not hold good.

After either Syme's or Pirogoff's operation, patients can run; which they cannot do after amputation of the leg in any part.

In cases of caries of the tarsus requiring amputation, it occasionally happens that the Surgeon cannot determine with certainty whether the morbid condition is limited to the anterior range of tarsal bones, or extends so far backwards as seriously to implicate the astragalus and calcaneum: and he is consequently unable to decide whether the condition of the foot admits of removal by Chopart's operation, or requires disarticulation at the ankle-joint. In these circumstances all doubt will be cleared away by making an incision across the dorsum of the foot in the line of the astragalo-scapoid and calcaneo-cuboid articulations; these are then opened, and the state of the bones is examined. If the astragalus and calcaneum be sound, or but slightly diseased on their anterior aspect, Chopart's operation may be done, and any carious bone left behind gouged away. If, on the contrary, these bones be found to be deeply implicated, the flap may be dissected back for about an inch, and disarticulation at the ankle-joint proceeded with.

Results.—The amputation of a toe, of a metatarsal bone, or even of a portion of the metatarsus, is but very seldom attended with fatal consequences. Should death occur, it must be the result of an accidental attack of tetanus, erysipelas, or pyæmia. Disarticulation at the ankle-joint, though necessarily somewhat more dangerous, is yet one of the most successful operations in Surgery, the mortality attending it being but very small.

The statistics of uncomplicated cases from the practice of Socin, Volkmann, and Max Schede, under antiseptic treatment, show 65 cases, with 2 deaths, 1 in a woman, aged 77, and 1 re-amputation. Those of Bruns, Bardeleben and Billroth, in the pre-antiseptic period, show 39 cases, with 10 deaths, 8 of which were from pyæmia. The highest mortality was from Pirogoff's operation, of which there were 13 cases, with 5 deaths, 4 from pyæmia and 1 from erysipelas.

AMPUTATION OF THE LEG.—The selection of the line of amputation must depend upon the extent of the disease or injury, but, whenever practicable, the operation should be performed low down: the mortality diminishing in proportion as the limb is removed near to the ankle. Surgeons used formerly, even where the disease or injury was limited to the foot, to amputate immediately below the knee, or, as it was said, "at the seat of election," in all those cases in which the patient would be obliged to wear a common wooden pin, the long leg-stump being highly inconvenient when the patient rested on his bent knee: whereas, in those individuals who could afford the expense of a well-constructed artificial limb, the amputation, when practicable, was done in the lower part of the leg. But this difficulty has been removed by the introduction of a short wooden pin, in the socket of which the stump may be fixed in the extended position: and amputation in all admissible cases should consequently, even amongst the poorer classes, be done as low down as possible.

The number of arteries divided will depend upon the situation of the

amputations. Holden lays down as a general rule that in amputations one inch below the head of the fibula, only one main artery—the popliteal—is divided. At two inches two arteries—the anterior and posterior tibial—and at three inches three, are cut, the peroneal being divided in addition to the two others.

Flap Amputation of the Leg by Transfixion, which was at one time the operation usually performed in this country, is performed in the following way. The surgeon stands with his left hand to the part to be removed, while the assistant, whose duty it is to retract the flaps, takes his stand opposite to the surgeon. In the *right* limb, the point of the knife is entered at the posterior edge of the tibia, carried downwards for a distance of one inch and a half to two inches, then across the front of the leg to the posterior border of the

Fig. 70. Amputation of the Right Leg. Transfixion of the Posterior Flap.

tibia, up which the incision is made to extend to a corresponding distance. In the *left* leg the same incision commences on the fibular side of the limb, and terminates on the tibial. The flap thus formed, which should be broad and well rounded, is next dissected up by a few touches of the point of the knife, and transfixion of the limb is made by passing the blade across behind the bones, from one angle of the incision to the other (Fig. 70), taking care not to pass the knife between the bones instead of behind them. The posterior flap is then formed by cutting obliquely downwards and backwards: it should be about three inches long. The bones are next cleared by a double sweep of the knife, and the interosseous soft parts divided by carrying the instrument in a figure-of-8 way between and round the bones. In doing this, special care must be taken not to direct the edge upwards, so as to split either of the tibial arteries, more particularly the anterior; for, as the vessel retracts above

the membrane, its ligature is no easy matter. If the amputation be performed just below the knee, it is possible that the popliteal trunk may be divided above its bifurcation, and thus only one artery may require ligature.

Fig 71.—Amputation of the Leg by the Long Posterior Flap. Sawing the Bones

sawing the bones the fibula must be divided first, as otherwise it may be fractured above the line of amputation. It is better to commence sawing on the tibia till the saw has entered a short distance, and then by sinking or

Fig 72 —Amputation of the Leg by Teale's Method

raising the hand, according to the side on which the operation is being performed, the saw is brought to bear on the fibula, which is completely divided before the tibia is finished (Fig. 71). After the removal of the limb, the sharp anterior edge of the tibia must be sliced off obliquely, to lessen the risk of sloughing of the flap from pressure upon a sharp ridge of bone.

If the limb be very muscular, a large mass of the muscles of the calf will be left in the posterior flap; this will be a good deal in the way during treatment, as its weight tends to displace the flap. In some cases I have advantageously removed the greater part of the muscular mass thus left, leaving little more than a skin flap. The inconveniences arising from the long posterior flap are, however, so great that it is better as a rule to adopt some other method of amputation.

In the *lower third of the leg*, **Teale's operation** (Fig. 72) can be performed according to the rules laid down on p. 68. The size of the wound may, however, be diminished by making part of the covering by retracting the soft parts from the bones, instead of entirely by flaps as in Teale's method. In this modified plan of operating an anterior flap is made equal in length to the diameter of the limb at the point at which the bones are to be sawn; it should be almost rectangular in shape, merely having the angles rounded off. A very short posterior flap may be cut to meet this by carrying the knife behind the limb somewhat obliquely from one end of the first incision to the other. The soft parts are then retracted by the knife, or better by the periosteal elevator, thus saving the periosteum, and the bone is sawn an inch or more above the angle of the flaps. As in Teale's method, the flaps should contain all that can be taken from the bones, for in this situation they are somewhat liable to slough. The bones in this part of the leg occupy almost the whole thickness of the limb, and it is necessary, therefore, to make the anterior flap equal to the diameter in length, so that the scar may be behind them. If there is any difficulty in retracting the soft parts, Lister recommends that the incision should be carried, on the fibular side, as high as the point at which the bones are to be sawn, as this greatly facilitates their separation. In order to avoid unnecessary wounding of the anterior tibial artery, Teale recommends that the soft parts should be raised from the interosseous membrane with the thumb-nail.

In the *middle and upper thirds of the leg*, the bones lie more towards the anterior aspect of the limb, and consequently it is not necessary to cut so long an anterior flap in order that the cicatrix may be placed behind them. In these situations the anterior flap may be made equal in length to two-thirds of the diameter of the limb, and the posterior flap one-half the length of the anterior, the rest of the covering being made by retraction of the soft parts from the bones. The anterior flap should consist, at its lower edge, of skin and fat only, but it should be gradually deepened as it is raised, till at its base it contains almost all the muscle that can be obtained from the front of the limb (Fig. 73). In dissecting up the posterior flap, which should contain only skin and fat, the limb should be raised so that the Surgeon can more conveniently do what he is doing. Both flaps being held well out of the way, the muscles are next divided circularly, and the soft parts raised from the bones for a distance equal to at least one-third of the diameter of the limb. In doing this, care must be taken not again to wound the anterior tibial artery. Finally, the bones are sawn as high as possible. The sharp point of the tibia must be rounded off. In doing this, if the retraction of the soft parts have not already been done with a periosteal elevator, it is well carefully to raise the periosteum before applying the saw, as by so doing the tendency to necrosis is somewhat diminished, the periosteum not being torn away to a higher point than that at which the bone is actually sawn. In primary amputations the soft parts can

always be retracted without difficulty. In secondary amputations, when the parts are swollen, it may be necessary to make an incision upwards on one or both sides from the angle of union of the flaps towards the point at which the bones are to be sawn.

If from any cause there should not be sufficient skin available to form the long anterior flap, the **circular operation**, or the modification of it recommended by Liston, as described on p. 67, may be employed instead (see Fig. 24, p. 68). All these operations have the great advantage of getting rid of the heavy mass of the muscles of the calf, and that by the long anterior flap

Fig. 73. Amputation of the Leg by Long Anterior and Short Posterior Skin Flaps, with Circular Division of the Muscles.

secures in addition that the cicatrix shall be well behind the cut ends of the bones, and that there shall be a dependent opening for the exit of the discharges. The long anterior flap tends to keep itself in position by its own weight, and no strapping is required as in the amputation by the long posterior flap, and thus a great source of pain to the patient and of disturbance to the stump is avoided. There is also much less tendency to protrusion of the bone, as the weight of the flap is hardly sufficient to cause ulceration, if the end of the tibia has been carefully rounded.

Troves has obtained good results by the use of the **large external flap** recommended by Farabeuf for amputation at the seat of election. The flap is length to the diameter of the limb at the point where the bones are

ended. The incision which marks out the flap begins in front at this same end, and ends behind at a point $1\frac{1}{2}$ inch lower, whence an incision passes straight round the inner side of the limb. In dissecting up the flap the vessels must be cut through obliquely, and care taken that the anterior tibial artery is left uninjured on the deep surface of the flap.

Results.—The mortality after amputation of the leg was formerly very high, varying generally in different hospital reports from 50 to 30 per cent., the chief causes of death being pyæmia, gangrene of the stump and exhaustion. The death-rate was higher in secondary than in primary operations, and fell to 23·5 per cent. in cases in which the operation was performed for disease. So far as situation is concerned, as a general rule, the nearer the knee the greater the danger. The high death-rate formerly prevailing has now been much reduced. In the statistics published by Max Schede (p. 83), amongst the uncomplicated cases treated antiseptically, are 19 amputations for injury and 50 for disease, with only 1 death, and that was from erysipelas, in a patient who had previously suffered more than once from the disease. Amongst the uncomplicated cases treated by Bardeleben, Billroth, and Bruns, without antiseptics, were 28 for injury, with 15 deaths, and 87 for disease, with 25 deaths; 29 of the deaths were from pyæmia and 7 from septicæmia.

AMPUTATION THROUGH THE KNEE-JOINT, originally recommended in the sixteenth century by Hoin, and reintroduced by Velpeau, Markoe, and Brinton, has now found favour in this country and in America.

Amputation through the knee-joint may be performed in three different ways: 1, with a long anterior and a short posterior flap; 2, with lateral flaps; 3, with a long posterior and a short anterior flap.

1. The operation by means of a **Long Anterior and Short Posterior Flap** is thus performed. A long square flap, rounded at the corners, is made by entering the point of a short broad-bladed amputating-knife towards the anterior part of one condyle, carrying the incision downwards in a straight line for four or five inches, then across the limb, and cutting upwards to a point on the opposite side corresponding to that of entry. The integuments and the patella are then dissected from the front of the joint (Fig. 74). The articulation is thus opened; the ligaments are then successively divided, the limb being forcibly bent; and a posterior flap is formed by cutting from behind forwards, or by dissecting down behind the bones and then cutting backwards. The flap should be about $2\frac{1}{2}$ to 3 inches long. If made shorter than this, it is apt to retract up the back of the thigh. Indeed, in all cases there is a great tendency to this, even when the flap is of the length above given. The popliteal artery is divided, and, with the exception of the articular vessels, is the only one requiring ligature.

The management of the patella is an important question: some Surgeons advocating its removal and others its preservation. I think that it is decidedly better to leave it, as it forms an important protection to the end of the stump. If it be removed, the flap becomes so thinned as to incur danger of gangrene. I have practised the operation both ways, and have from my experience found it most advantageous to leave the patella. There is only one objection to this; and that is the chance of the patella being drawn up, as occasionally happens, upon the anterior part of the thigh. This is best prevented by cutting across the tendinous insertion of the quadriceps extensor during the operation.

The cartilage on the femur should be left untouched, as thus the cancellous structure is not opened, and one predisposing cause of pyæmia is avoided. The operation is not adapted to cases in which the joint is diseased; in them it is better to amputate through the condyles.

In the after-treatment great trouble may arise from accumulation of the

discharges in the synovial pouches. This can be prevented only by proper drainage and pressure. Before closing the wound, two long tubes must be put in, in such a way that their deep extremities lie in the extreme upper parts of the synovial pouches, and their lower ends at the angles of the wound. These tubes should not be touched till the third day; after that they may be drawn out half an inch or more at each dressing, and the projecting piece cut off. They must on no account be completely removed in order to shorten them, as it would be impossible to replace them. Should pus form in the synovial pouches from failure of the drainage, it will be recognised by the swelling, redness and pain, with fluctuation. A free incision must be made into it as soon as the condition is recognised, or the pus may burst through the limits of the synovial pouch, and burrow up the thigh beneath the vasti. These precautions for drainage are necessary in all amputations in which the synovial pouches are opened.

2. Stephen Smith disarticulates at the knee by **Lateral Flaps** in the following way: The incision is commenced in the middle line in front, about an inch below the tubercle of the tibia, and is carried downwards and backwards over

Fig 74.—Amputation through the Knee by Long Anterior Flap.

the side of the leg, until it reaches the under surface, where it is directed upwards and towards the median line. When that point is reached, it is carried directly upwards to the centre of the popliteal space. A second incision begins at the same point as the first, and pursues a similar direction on the opposite side of the limb, the two incisions meeting in the median line behind. The flaps are next raised, and the soft parts dissected up circularly until the joint is opened, and the leg then removed. The inner flap should be

the larger, because of the greater size of the inner condyle; the patella

is left. After this amputation, the stump presents the appearance represented in Fig. 75. The operation, which is in reality rather a modified circular method than a true amputation by lateral flaps, gives the most excellent results. Bryant, who has recorded twenty cases, speaks highly of it, and recommends that in raising the flaps the knife should be kept close to the head of the tibia so as to divide the coronary ligaments, and thus leave the semilunar cartilages closely encircling the condyles of the femur. "By this means the upper part of the synovial capsule is held down firmly to the condyles of the femur, and thus all the soft parts are kept well in place." This mode of operating was also described in 1872 by Brinton.

3. The operation with the **Long Posterior and Short Anterior Flap** has the great disadvantage that the posterior flap has an almost uncontrollable

Fig. 75.—Amputation at the Knee by Lateral Flaps.

tendency to retract, and it should never be undertaken when the covering can be obtained more extensively or entirely from the front. It may be readily performed in the following way. An incision is made directly across the knee-joint, just below the patella. The skin-flap thus formed is dissected back; and, the joint being opened above the patella, and the ligaments divided by a few touches of the knife, a long posterior flap is cut from the upper part of the calf of the leg, by passing the knife behind the tibia, and carrying it downwards for a suitable distance.

AMPUTATION THROUGH THE CONDYLES may be done in three different ways: 1, with a long anterior flap, including the patella or not; 2, by a modified circular method; 3, with a long posterior flap.

1. Carlen, of Worcester, was the first to employ the method of amputation by the **long anterior flap** in this situation. He took away the patella and made no posterior flap; but subsequent operators have found that without a

posterior flap the covering is frequently insufficient. The operation is therefore usually performed as follows: The finger and thumb of the left hand are placed on the two condyloid eminences of the femur, which serve as guides for the starting-points of the incision. A long anterior flap is then marked out, well rounded in shape, and reaching as low as the tubercle of the tibia. This is dissected up either with or without the patella. In cases in which the Surgeon is hesitating between excision and amputation, the joint may be examined before proceeding further and the operation determined on. When the anterior flap has been raised, the knife is passed behind the femur, and a posterior flap, equal in length to the anterior, is cut from within outwards. This flap contains the hamstring tendons, and usually a part of the muscles of the calf, and it consequently retracts considerably after being cut. The flaps being held back, the knife is swept round immediately above the cartilage-covered surfaces, and the saw carried through the bases of the condyles parallel to the articular surface of the femur, that is to say, somewhat obliquely to the

Fig. 70. Amputation through the Condyles by modified circular method.

axis of the shaft, the inner side being left a little longer than the outer. Gritti, an Italian Surgeon, has recommended that the patella should be left in the flap, and its cartilaginous surface sawn off so as to form a raw bony surface to be applied to the cut end of the femur. Sir William Stokes has modified Gritti's method by dividing the femur half an inch above the condyles instead of through them, thus making the sawn surface of the femur more equal in size to that of the patella, and diminishing the risk of the latter being drawn forwards and upwards off the end of the shaft.

2. Lister has recommended an amputation by a **modified circular method**, which is thus performed: "The Surgeon first cuts transversely across the front of the limb, from side to side, at the level of the tubercle of the tibia, and joins the horns of this incision by carrying the knife at an angle of forty-five degrees to the axis of the leg through the skin and fat. The limb being extended, he dissects up the posterior skin flap, and then proceeds to raise the flap of integument as in a circular operation, taking due care to avoid scoring

the subcutaneous tissue; and, dividing the hamstrings as soon as they are exposed, and bending the knee, he finds no difficulty in reaching the upper border of the patella. He then sinks the knife through the insertion of the quadriceps extensor (Fig. 76), and, having cleared the bone immediately above the articular cartilage and holding the limb horizontally, he applies the saw vertically, and at the same time transversely, to the axis of the limb (not of the bone), so as to ensure a horizontal surface for the patient to rest on." When the soft parts are much thickened, as in disease of the knee-joint, the leg may be removed by dividing the ligamentum patellæ and opening the joint as early as possible. After this the condyles of the femur can usually be protruded and sawn off without difficulty, and the patella removed last of all. If there is still difficulty in protruding the femur an incision may be carried upwards on the outer side as far as may be necessary. The advantage of this operation is that, if it be carefully performed, the chance of sloughing is reduced to a minimum. The pouches of the synovial membrane of the knee must be carefully drained as before described.

3. Amputation through the condyles by the **long posterior flap** should never be performed, unless under exceptional circumstances no other flaps can be obtained.

There is a point of practice that I have found useful in these amputations: viz. to round off with the saw the sharp edge left on the condyle after the removal of its cartilaginous surface, as otherwise this may press injuriously upon the flap.

These amputations present four great advantages over those higher up:

1. As the medullary canal is not opened, the risk of septic osteomyelitis and consequent pyæmia is diminished.
2. The limb being removed at a greater distance from the trunk, the shock will be less and the rate of mortality diminished.
3. The patient is provided with a long thigh-stump, which gives increased leverage in using an artificial limb.
4. When the amputation is practised with the long anterior flap containing the patella, or taking the skin from over it, the end of the stump will be protected by the tough integument naturally formed in front of the knee, which will admit of pressure being made upon it without fear of excoriation: the cicatrix being drawn up behind the end of the stump, and altogether away from its surface.

Results of Amputation through the Knee-joint or Condyles of the Femur.—So far as life is concerned, these operations have been successful. In the American Civil War, of 132 cases, 64 died, giving a mortality of 48·4 per cent. Of these 49 were primary amputations: the deaths among which were 16, or 32·6 per cent. Brinton gives 62 cases of amputation through the knee for disease, with 14 deaths, or 22·6 per cent.

Max Schede gives the results of amputation through the knee-joint in civil practice as follows: for injury, 314 cases, 103 deaths, or 32·8 per cent.; for disease, 123 cases, 30 deaths, or 24·4 per cent.; through the condyles, for injury, 111 cases, 40 deaths, or 36·1 per cent.; for disease, 60 cases, 15 deaths, or 25 per cent.; Gritti's operation for injury, 25 cases, 4 deaths, or 16 per cent.; for disease, 19 cases, 5 deaths, or 26·3 per cent.

AMPUTATIONS OF THE THIGH are commonly required both for accident and for disease. As a rule the operation is most efficiently performed by the antero-posterior flap method, the covering being raised by dissection, not by transsection. Excellent results may also be obtained in all parts of the thigh

by the circular and modified circular operations. Amputation just above the knee was formerly most often performed by equal lateral flaps cut by *trausfixion*. The fleshy flaps of uniform thickness thus obtained were supposed to form a better covering than the thinner structures in front. But the lateral flaps have the disadvantage of leaving the scar over the bone, and they are difficult to keep in position, and consequently few Surgeons now adopt this method. In other parts of the thigh lateral flaps cannot be conveniently made, as the end of the bone is apt to be drawn up into the angle of the wound, and to project between the flaps, which fall away behind it. In amputation in the lower or middle third, a tourniquet may be applied high on the limb: but when the operation is done in the upper third, there is no space for the application of this instrument, so the hæmorrhage must be arrested by the application of the india-rubber bandage as described on p. 47, by the aortic tourniquet, or by an assistant compressing the artery as it passes over the brim of the pelvis (Fig. 19, p. 53). In whatever situation the Surgeon

Fig. 77. Amputation of the Lower Third of the Thigh by Lateral Flaps

amputates, he must be careful to carry the knife so as not to split the femoral artery or vein.

Amputation above the Knee by Lateral Flaps, or Vermale's Operation, is thus performed: The outer flap should always be made first. The point of the knife, being entered in the middle of the thigh, about three inches above the upper border of the patella, is carried close round the bone and brought out through the centre of the ham; the flap is then cut downwards and outwards; the knife, being entered again in the upper angle of the incision, is carried close round the bone to its inner side, and the inner flap made by a sweeping cut (Fig. 77). Unless the blade be kept in contact with the bone in this situation, the femoral artery is very apt to be split. The flaps being then retracted, the bone is cleared by two sweeps of the knife, and sawn about four inches above its articular surface.

In all amputations of the thigh by the **Antero-Posterior Flap** method, more or less trouble is apt to arise from the posterior flap being displaced ~~inwards~~ by the divided flexor muscles, which, owing to their great length, for a very considerable distance. Even when the covering may at ve seemed abundant the edges of the wound may separate, leaving a

that no button-hole apertures be made through the heel flap. This may easily be avoided when the soft structures are thickened and infiltrated by inflammatory products: but, if the operation be required for injury, great care is required in digging out the heel, the integuments of the posterior part of the *os calcis* being very thin and adherent to the bone. It is also of importance that the first incision should be (Figs. 62, 63) distinctly inclined backwards towards the heel, and not forwards into the sole of the foot. Unless this be done, a large cup-shaped flap will be left, in which blood and discharges may accumulate, and retard healing. If union takes place by the second intention, bagging of discharges in the flap must be prevented by uniform elastic pressure and bandaging. The tendency to sloughing occurs chiefly in primary amputations. It has frequently been stated that it is necessary, in order to ensure the vitality of the flap, to cut the posterior tibial artery "as long as possible," and it is this as much as anything that has led to the production of the large cup-shaped flaps which are so difficult to dissect off the *os calcis*, and which so often slough. An examination of the vascular

Fig. 62. Line of Incision for Pirogoff's Operation—modified by Oblique Section of the *Os Calcis*.

supply will show that the posterior tibial artery may be cut close to the base of the flap, without interfering with the chief vessels supplying it. The distribution of vessels to the part is as follows. On the outer side, the peroneal artery, after giving off the anterior peroneal, is continued along the posterior aspect of the fibula to the outer side of the *os calcis*. On the inner side a branch of considerable size arises from the posterior tibial artery, about one inch above the ankle-joint, and passes down to the inner side of the *os calcis*, running behind the inner malleolus and accompanying the cutaneous nerve from the posterior tibial to the heel. There is thus a trunk on each side running down to the heel behind the malleolus, and these two communicate freely with each other, superficially over the cutaneous surface of the *tendo Achillis*, and deeply between the tendon and the ankle-joint; and they terminate by anastomosing by long loops on the under surface of the posterior part of the *os calcis*. It is upon these anastomosing loops that the vitality of the flap depends; and as they lie much nearer the bone than the skin it is evident that, unless the knife be kept hard upon the bone during

the whole dissection of the flap, they will be divided in large numbers, greatly endangering its vitality. In the operation as performed by Syme, the dissection of the flap is commenced from the most prominent part of the tubercles of the os calcis, and the knife can be kept in constant contact with the bone with the greatest ease. If, on the contrary, the incision extend far into the sole of the foot in front of the tubercles of the os calcis, it is almost impossible to dissect the flap back without the point of the knife being directed into its under surface and the vascular loops being divided.

This operation is a most useful one in all cases requiring removal of the

Fig. 67.—Pirogoff's Operation. Sawing the Os Calcis obliquely downwards and forwards.

whole foot. The mortality attending it is but small. The stump that is left admits of the whole weight of the body being borne upon it.

Various modifications of Syme's amputation may at times be practised with advantage, when the soft parts covering the heel are not in a condition to form a good basis of support. In these circumstances, the flaps may be fashioned on the side instead of from behind; and in this way I have more than once formed an excellent covering. These lateral flaps should not, however, be made in any case that admits of disarticulation at the ankle in the ordinary way, as they never afford so good a basis of support as the integuments of the heel.

Pirogoff's Amputation is characterised by the preservation of the posterior portion of the os calcis. In operating on the right side, an incision is carried across the sole of the foot from the tip of the external malleolus to the corre-

this may readily enough be done by dissecting the head out of the acetabulum with a strong scalpel or bistoury.

Results.—The mortality after amputation of the thigh is very considerable when the operation is done for injury, more particularly for compound fracture of the femur itself. The mortality in the older statistics (p. 89) amounted to 59·7 per cent. In the more recent statistics of University College Hospital it is 16·1 per cent. Shock and traumatic gangrene of the stump are the chief causes of death.

The result of amputation of the thigh for disease of the knee-joint depends entirely upon whether the affection is acute or chronic. In acute suppurative disorganisation of the knee, amputation of the thigh is most fatal: indeed, so high is the rate of mortality, that it is doubtful whether it is proper to perform the operation in that stage of the affection. In chronic knee-joint disease, on the other hand, the operation is most satisfactory and successful: death seldom resulting unless the operation has been deferred too long. The average mortality of complicated and uncomplicated cases together in the older statistics was 32·5 per cent. In the more recent statistics of University College Hospital it is 23·5. Max Schede's statistics, in which complicated cases are excluded, gives 63 cases with only one death. The mortality, as before stated (p. 86), increases as the trunk is approached.

AMPUTATION AT THE HIP-JOINT.—This formidable operation is of comparatively recent introduction into surgery. During the early part and middle of the last century its practicability was warmly debated in France. It was performed on animals experimentally. It was found that some patients affected with ergotism, whose lower extremities had become gangrenous, and had separated at the hip-joint, survived: and, at last, in the year 1773, the first successful amputation of the kind was performed by Perrault of St. Maurice. In the next year, the operation was done in England by Kerr of Northampton, on a girl aged 12, affected with hip-disease and lumbar abscess. The operation was unjustifiable in such a case, but the patient lived 17 days, and thus its practicability was demonstrated. Larrey performed it in 1793 for the first time for gun-shot injury; and since that time the operation has been established in surgical practice, civil as well as military. The operation was first performed successfully in England in 1812, by Brownrigg of Plymouth, on a man whose thigh had been broken in the Peninsular war a year previously.

Amputation at the hip-joint has been performed in a variety of ways which it is not necessary to detail. The following will be described: 1. by combined circular and external vertical incisions; 2. by antero-posterior flaps; 3. by the oval method.

1. The amputation by **combined circular and external vertical incisions** is that usually known as *Furneaux Jordan's method*, although the operation, as now performed, differs in many respects from the description given by that Surgeon. The patient's body is drawn well to the edge of the table, and turned slightly on to the sound side. The thigh of that side is secured in the flexed position by two bandages: one attached to the thigh above the knee by a clove-hitch, the two ends of which are passed round the neck and knotted under the arm of the same side; whilst the second bandage is passed round the sound thigh and secured to the leg of the table beneath the patient's head. The circulation through the limb is controlled by

Esmarch's elastic cord applied in the manner described on p. 47, or by an aortic compressor. An amputating knife of moderate length is to be chosen. The skin and subcutaneous tissues are divided circularly at the junction of the middle and lower thirds of the thigh, and after reflecting them for at least two inches, the muscles are divided circularly down to the bone. The femoral vessels and any others which can be recognized are now ligatured. A vertical incision is next made upwards along the outer side of the thigh from the circular cut to a point midway between the great trochanter and the iliac crest (Fig. 79). The muscles, with or without the periosteum, are turned off the shaft of the femur, and the head is turned out of the acetabulum by dividing the capsule on to the neck of the bone, whilst an assistant rotates the limb according to the direction of the Surgeon. Oozing vessels may now

Fig. 79.—Fournier-Jordan's Amputation at the Hip-joint.

be secured before removing the tourniquet. The raw surface is necessarily extensive, and free provision must be made for drainage.

2. Amputation at the hip by **antero-posterior flaps** is the easiest and most speedy method. It consists in making a large and thick anterior flap by transfixion, and a short posterior one from the gluteal region and back part of the thigh. In order to perform this operation properly, the patient's body must be brought well forward upon the edge of the table, so that the nates project beyond it, and be stented by strong bandages. One of these must be passed between the sound thigh and the perineum, and attached to the upper end of the table; another should be carried across the pelvis to the lower end; and the sound limb must be tied to the leg of the table.

The Surgeon must have three assistants on whom he can rely. Assistant No. 1 takes charge of the flap, compressing the femoral vessels; and, in the absence of the abdominal compressor, on his trustworthiness the patient's life

is mainly dependent. Assistant No. 2 holds the limb; flexing it slightly on the abdomen in the first stage of the operation, whilst the anterior flap is being made; forcibly abducting, extending, and rotating it outwards during the second stage, when the Surgeon is opening the capsule of the joint; and extending and rotating inwards during the time the posterior flap is being cut. On the way in which he performs these duties the facility with which the Surgeon performs the operation is mainly dependent. To Assistant No. 3 is consigned the care of the instrument used for controlling the circulation. After the removal of the limb, Assistant No. 2 aids the Surgeon in ligaturing the arteries. These preliminaries having been arranged, and the duty of each assistant assigned to him, the operation is to be performed in the following way:

The Surgeon, standing on the left side of the limb to be removed, feels for the bony points which guide his knife, viz. the tuber ischii and the anterior

Fig. 80.—Amputation at the Hip-joint: Formation of Anterior Flap in Left Limb

superior spine of the ilium. The knife, which must have a blade twelve inches long, is entered, and the flap made, in different ways, according to the side of the body on which the operation is performed. If it be on the *left* side, the knife should be entered about two finger's breadths below the anterior superior spine of the ilium, and carried deeply in the limb behind the vessels, directly across the joint, its point being made to issue near the tuberosity of the ischium well behind the prominent ridge formed by the tendon of the adductor longus (Fig. 80). In transfixing on this side, care must be taken not to wound the scrotum or the opposite thigh; the back of the knife must run parallel to Poupart's ligament, and the point must not be directed too much upwards, lest it enter the abdominal cavity. As soon as the point of the knife passes the head of the bone, the handle must be raised so as to direct the point beneath the femoral vessels, lest they be wounded. The aortic compressor does not control the iliac vein, and should the femoral vein be punctured above its

last valve, most dangerous regurgitant hæmorrhage would take place. Transfixion being accomplished, the anterior flap must be cut rapidly downwards about six or eight inches in length. The assistant who is to take charge of the flap passes both hands into the wound above the back of the knife, and grasps the femoral artery firmly between his fingers and thumbs (Fig. 82). As soon as he has thus secured the vessel, the Surgeon turns the edge of the knife forwards and completes the anterior flap. In doing this, care must be taken not to make the flap pointed. This is best done by keeping the edge of the knife turned slightly towards the bone till the point is reached at which it is to be brought out. Also, the assistant who holds the limb must take care not to extend it too soon, but to keep it flexed and slightly adducted until the

Fig. 81.—Amputation at the Hip-joint: Formation of Anterior Flap in Right Limb.

anterior flap is completely cut, and the assistant who has charge of the flap must be careful not to raise it up too much nor to squeeze it laterally in grasping the vessel. As soon as the knife is brought out, the assistant holding the vessel raises the flap upwards towards the abdomen. The limb, which has so far been raised, slightly flexed and adducted, must now be forcibly extended, abducted, and rotated outwards; the capsule of the joint is then to be opened by a firm cut with the point of the knife. As soon as this is done, the head of the femur starts out of the socket and the operator touches the round ligament with the point of the knife. The assistant now allows the limb to hang down, and the head of the femur becomes separated by some distance from the acetabulum, and the posterior part of the capsule is brought into view and put on the stretch. This is divided with the point of the knife, and immediately it is done the assistant puts the limb in an extended position in a line with

the body, and at the same time rotates it inwards so that the trochanter shall not catch the knife; the heel of the knife is then passed over the trochanter, and the posterior flap rapidly cut by carrying the knife downwards and backwards through the thick muscles in this situation. The posterior flap may be about four inches in length; but this must, of course, vary according to the length of the anterior flap. When the amputation is performed on the *right* side, the anterior flap is made by entering the knife just above the tuberosity of the ischium, and bringing it out two fingers' breadth below the anterior superior spine of the ilium (Fig. 81); the remaining steps of the operation being performed as in the last case. In transfixing from the inner side, if

FIG. 82. Amputation at Hip-joint: Compression of Femoral Artery in Anterior Flap.

the point of the knife be directed too much upwards, it may enter the thyrid foramen.

In order to avoid the inconvenience caused by standing in a cramped position between the patient's thighs, many Surgeons transfix from the outer side on the right limb as well as on the left.

In consequence of the extent to which the limb that is about to be removed may have been injured, or encroached upon by disease, it is not always easy to make the anterior flap of the size or shape described. A little management on the part of the Surgeon will, however, enable him to take the requisite amount of covering from the outer or inner parts by inclining the point or the heel of the knife downwards, as the case may require; or he may make the anterior flap by dissection, instead of by transfixion.

When the femur is entire and unbroken, Assistant No. 2 uses it as a lever, bringing the lower end of it in the second stage of the operation

downwards and outwards, thus causing the head of the bone to press against the anterior part of the capsule, and to start out with a peculiar sucking noise as soon as the latter is opened. Should the bone have been fractured high up, this movement cannot be given to it and the operation is rendered somewhat more difficult. In such a case the Surgeon must grasp the upper end of the femur below the trochanters, so as to steady and push it back as he is disarticulating its head. In two of the cases in which I have amputated at the hip-joint, it has been necessary to do this—in one, in consequence of the crushing of the bone, two inches below the trochanters, by a railway accident: in the other, in consequence of its spontaneous fracture at the junction of its upper and middle thirds, in a case of rapidly growing malignant disease of the bone.

As a further precaution against hæmorrhage the Assistant who steadies the body may press his thumb well down into the iliac fossa so as to compress the artery against the brim of the pelvis. If the tourniquet or compressor is acting efficiently there is no hæmorrhage from the posterior flap, but should the instrument be imperfectly applied there will be free hæmorrhage from the gluteal and sciatic vessels, which must be arrested by the Assistants, who should be ready to compress them with their fingers or with dry sponges, or to seize them in force-pressure forceps. The arteries may then be ligatured one by one, as the Assistant exposes them. If the other Assistant have a good hold of the femoral, the vessels in the posterior flap may be tied first: but if the femoral be insecurely held, it must be first tied. The femoral arteries, both superficial and deep, will be found to be cut long, and to project from the muscles by which they are surrounded, so as very readily to be seized by the fingers or forceps, pulled out, and ligatured. The arteries in the posterior flap and on the inner side of the joint will be found in the intermuscular septa. The flaps are to be brought together by sutures, two or three drainage-tubes of large size must be inserted, and after the dressing has been applied, a turn of a broad bandage may be passed round the abdomen, and the end brought up from behind under the stump so as to support it.

3. The **oval amputation** may be performed in the following way: The patient is placed on his sound side and the thigh of that side is secured with bandages as in the first method above described. The patient's body must be further steadied by an Assistant placed opposite the shoulders. Another Assistant takes charge of the thigh, and a third, who stands opposite the Surgeon, will take the vessel by thrusting the fingers of one hand into the wound and grasping the artery between them and his thumb. The patient being thus prepared, and the india-rubber band or aortic compressor applied, the Surgeon stands so as to have his left hand to the flaps, that is to say, behind for the right thigh, and in front for the left. An amputating knife of moderate length is to be chosen. The incision is commenced about two inches above the trochanter and carried firmly down to the bone and along the femur to about six or seven inches below the upper end of the bone. At this point the incision is made to bifurcate, one part being carried in a curved direction forwards for about two inches and the other backwards in the same way (Fig. 83, *b*). This marks the point at which the transverse part of the incision is to be made. The limb is now abducted, and, if the first incision has been made with sufficient firmness, the operator will be able to push his thumb into the longitudinal slit which has been made in the lower parts of

the two smaller glutei. The muscles thus being put on the stretch by the Surgeon's thumb, the point of the knife is made to cut over the trochanter and down the upper part of the bone, separating the muscles attached to it, first in front and then behind. The limb is then forcibly adducted, and the Assistant at the same time tries to lift the head of the femur out by putting one of his hands on the inner side of the thigh as high up as possible. The operator then opens the joint by making a firm cut in the line of the superficial incision, so as to make a vertical slit in the capsule and divide the cotyloid ligament, and thus to render dislocation more easy. Another incision is then carried transversely through the capsule in the line of its attachment. The head of the bone then starts from the socket, and the point of the knife is inserted so as to divide the round ligament. If the head does not come out readily, the Assistant may seize the exposed trochanter with a

Fig. 52. Lines of Incision for Amputation at Hip. *a*, Fournier-Jordan's Method; *b*, Oval Method. *c*, *d*, Upper Border of Trochanter.

pair of lion-forceps and drag it forcibly outwards. The remainder of the capsule on the inner side is then cut, and the Assistant can now lay hold of the trochanter and pull it forcibly out of the wound, and the operator, getting his knife to the inner side while he holds the soft parts out of the way with his left hand, gradually separates the bone from its attachments till it is exposed as low as is required. During this part of the operation the limb must still be adducted to the greatest possible extent. Having reached the point at which the commencement of the transverse part of the incision has already been marked, the Surgeon turns the edge of the knife away from the bone and cuts across to the inner side of the limb, thus completing the amputation. During this part of the operation the Assistant must bring the limb into a straight line with the trunk. The artery must be compressed by another Assistant with one hand in the upper part of the wound. If the bone be very muscular it is a good plan, after having enucleated the upper part of the femur, to complete the circular part of the incision by cutting from

part of the thigh from the trochanters to the lower end, where the skin over the patella is included in the anterior flap.

In some instances in which the tissues at the posterior part of the thigh are much diseased or injured, whilst those on the anterior aspect of the limb are sound, a very good stump may be fashioned by making a long square anterior flap, and then cutting at one stroke of the knife through the soft parts at the posterior aspect of the limb, in a somewhat oblique direction from below upwards. The anterior flap, when laid down, will form the cushion at the end of the stump.

Amputation in the lower third of the thigh is sometimes undertaken for

Fig. 78. — Amputation of the Thigh: Flaps cut from without inwards.

spontaneous gangrene of the foot. In such cases the best method is to divide the soft parts on the front of the thigh circularly down to the bone at the level of the upper border of the patella. A very short posterior skin flap is raised, and the soft parts are reflected for at least the length of the diameter of the limb before sawing the bone. Scarcely any interference with the vascular supply of the part is thus caused.

Amputation through the Trochanters may sometimes be advantageously practised, either in severe compound fractures of the lower part of the thigh, or in cases of non-malignant tumours of the lower and middle thirds of the femur: and thus the more severe and dangerous operation of disarticulation at the hip may be avoided. Indeed, should it be found, after section of the bone, that it is so much injured or diseased as to require removal at the joint,

this may readily enough be done by dissecting the head out of the acetabulum with a strong scalpel or bistoury.

Results.—The mortality after amputation of the thigh is very considerable when the operation is done for injury, more particularly for compound fracture of the femur itself. The mortality in the older statistics (p. 89) amounted to 50·7 per cent. In the more recent statistics of University College Hospital it is 46·1 per cent. Shock and traumatic gangrene of the stump are the chief causes of death.

The result of amputation of the thigh for disease of the knee-joint depends entirely upon whether the affection is acute or chronic. In acute suppurative disorganisation of the knee, amputation of the thigh is most fatal; indeed, so high is the rate of mortality, that it is doubtful whether it is proper to perform the operation in that stage of the affection. In chronic knee-joint disease, on the other hand, the operation is most satisfactory and successful: death seldom resulting unless the operation has been deferred too long. The average mortality of complicated and uncomplicated cases together in the older statistics was 32·5 per cent. In the more recent statistics of University College Hospital it is 23·5. Max Schede's statistics, in which complicated cases are excluded, gives 63 cases with only one death. The mortality, as before stated (p. 86), increases as the trunk is approached.

AMPUTATION AT THE HIP-JOINT.—This formidable operation is of comparatively recent introduction into surgery. During the early part and middle of the last century its practicability was warmly debated in France. It was performed on animals experimentally. It was found that some patients affected with ergotism, whose lower extremities had become gangrenous, and had separated at the hip-joint, survived: and, at last, in the year 1773, the first successful amputation of the kind was performed by Perrault of St. Maurice. In the next year, the operation was done in England by Kerr of Northampton, on a girl aged 12, affected with hip-disease and lumbar abscess. The operation was unjustifiable in such a case, but the patient lived 17 days, and thus its practicability was demonstrated. Larrey performed it in 1793 for the first time for gun-shot injury; and since that time the operation has been established in surgical practice, civil as well as military. The operation was first performed successfully in England in 1812, by Brownrigg of Plymouth, on a man whose thigh had been broken in the Peninsular war a year previously.

Amputation at the hip-joint has been performed in a variety of ways which it is not necessary to detail. The following will be described: 1. by combined circular and external vertical incisions: 2. by antero-posterior flaps: 3. by the oval method.

1. The amputation by **combined circular and external vertical incisions** is that usually known as *Furneaux Jordan's method*, although the operation, as now performed, differs in many respects from the description given by that Surgeon. The patient's body is drawn well to the edge of the table, and turned slightly on to the sound side. The thigh of that side is secured in the flexed position by two bandages: one attached to the thigh above the knee by a clove-hitch, the two ends of which are passed round the neck and knotted under the arm of the same side: whilst the second bandage is passed round the sound thigh and secured to the leg of the table beneath the patient's head. The circulation through the limb is controlled by

posterior flap the covering is frequently insufficient. The operation is therefore usually performed as follows: The finger and thumb of the left hand are placed on the two condyloid eminences of the femur, which serve as guides for the starting-points of the incision. A long anterior flap is then marked out, well rounded in shape, and reaching as low as the tubercle of the tibia. This is dissected up either with or without the patella. In cases in which the Surgeon is hesitating between excision and amputation, the joint may be examined before proceeding further and the operation determined on. When the anterior flap has been raised, the knife is passed behind the femur, and a posterior flap, equal in length to the anterior, is cut from within outwards. This flap contains the hamstring tendons, and usually a part of the muscles of the calf, and it consequently retracts considerably after being cut. The flaps being held back, the knife is swept round immediately above the cartilage-covered surfaces, and the saw carried through the bases of the condyles parallel to the articular surface of the femur, that is to say, somewhat obliquely to the

Fig. 70.—Amputation through the Condyles by modified circular method

axis of the shaft, the inner side being left a little longer than the outer. Gritti, an Italian Surgeon, has recommended that the patella should be left in the flap, and its cartilaginous surface sawn off so as to form a raw bony surface to be applied to the cut end of the femur. Sir William Stokes has modified Gritti's method by dividing the femur half an inch above the condyles instead of through them, thus making the sawn surface of the femur more equal in size to that of the patella, and diminishing the risk of the latter being drawn forwards and upwards off the end of the shaft.

2. Lister has recommended an amputation by a **modified circular method**, which is thus performed: "The Surgeon first cuts transversely across the front of the limb, from side to side, at the level of the tubercle of the tibia, and joins the horns of this incision by carrying the knife at an angle of forty-five degrees to the axis of the leg through the skin and fat. The limb being elevated, he dissects up the posterior skin flap, and then proceeds to raise the ring of integument as in a circular operation, taking due care to avoid scoring

this may readily enough be done by dissecting the head out of the acetabulum with a strong scalpel or bistoury.

Results.—The mortality after amputation of the thigh is very considerable when the operation is done for injury, more particularly for compound fracture of the femur itself. The mortality in the older statistics (p. 89) amounted to 59·7 per cent. In the more recent statistics of University College Hospital it is 46·1 per cent. Shock and traumatic gangrene of the stump are the chief causes of death.

The result of amputation of the thigh for disease of the knee-joint depends entirely upon whether the affection is acute or chronic. The operation was first performed successfully in England in 1812, by Brownrigg of Plymouth, on a man whose thigh had been broken in the Peninsular war a year previously.

Amputation at the hip-joint has been performed in a variety of ways which it is not necessary to detail. The following will be described: 1. by combined circular and external vertical incisions: 2. by antero-posterior flaps: 3. by the oval method.

1 The amputation by **combined circular and external vertical incisions** is that usually known as *Furneaux Jordan's method*, although the operation, as now performed, differs in many respects from the description given by that Surgeon. The patient's body is drawn well to the edge of the table, and turned slightly on to the sound side. The thigh of that side is secured in the flexed position by two bandages: one attached to the thigh above the knee by a clove-hitch, the two ends of which are passed round the neck and knotted under the arm of the same side; whilst the second bandage is passed round the sound thigh and secured to the leg of the table beneath the patient's head. The circulation through the limb is controlled by

Esmarch's elastic cord applied in the manner described on p. 47, or by an aortic compressor. An amputating knife of moderate length is to be chosen. The skin and subcutaneous tissues are divided circularly at the junction of the middle and lower thirds of the thigh, and after reflecting them for at least two inches, the muscles are divided circularly down to the bone. The femoral vessels and any others which can be recognized are now ligatured. A vertical incision is next made upwards along the outer side of the thigh from the circular cut to a point midway between the great trochanter and the iliac crest (Fig. 79). The muscles, with or without the periosteum, are turned off the shaft of the femur, and the head is turned out of the acetabulum by dividing the capsule on to the neck of the bone, whilst an assistant rotates the limb according to the direction of the Surgeon. Oozing vessels may now

Fig. 79.—Fournier's Amputation at the Hip-joint.

be secured before removing the tourniquet. The raw surface is necessarily extensive, and free provision must be made for drainage.

2. Amputation at the hip by **antero-posterior flaps** is the easiest and most speedy method. It consists in making a large and thick anterior flap by transfixion, and a short posterior one from the gluteal region and back part of the thigh. In order to perform this operation properly, the patient's body must be brought well forward upon the edge of the table, so that the nates project beyond it, and be steadied by strong bandages. One of these must be passed between the sound thigh and the perineum, and attached to the upper end of the table; another should be carried across the pelvis to the lower end; and the sound limb must be tied to the leg of the table.

The Surgeon must have three assistants on whom he can rely. Assistant No. 1 takes charge of the flap, compressing the femoral vessels; and, in the absence of the abdominal compressor, on his trustworthiness the patient's life

is mainly dependent. Assistant No. 2 holds the limb; flexing it slightly on the abdomen in the first stage of the operation, whilst the anterior flap is being made; forcibly abducting, extending, and rotating it outwards during the second stage, when the Surgeon is opening the capsule of the joint; and extending and rotating inwards during the time the posterior flap is being cut. On the way in which he performs these duties the facility with which the Surgeon performs the operation is mainly dependent. To Assistant No. 3 is consigned the care of the instrument used for controlling the circulation. After the removal of the limb, Assistant No. 2 aids the Surgeon in ligaturing the arteries. These preliminaries having been arranged, and the duty of each assistant assigned to him, the operation is to be performed in the following way:

The Surgeon, standing on the left side of the limb to be removed, feels for the bony points which guide his knife, viz. the *tuber ischii* and the anterior

Fig. 80.—Amputation at the Hip-joint. Formation of Anterior Flap in Left Limb

superior spine of the ilium. The knife, which must have a blade twelve inches long, is entered, and the flap made, in different ways, according to the side of the body on which the operation is performed. If it be on the *left* side, the knife should be entered about two finger's breadths below the anterior superior spine of the ilium, and carried deeply in the limb behind the vessels, directly across the joint, its point being made to issue near the tuberosity of the ischium well behind the prominent ridge formed by the tendon of the *adductor longus* (Fig. 80). In transtfixing on this side, care must be taken not to wound the scrotum or the opposite thigh; the back of the knife must run parallel to Poupart's ligament, and the point must not be directed too much upwards, lest it enter the abdominal cavity. As soon as the point of the knife passes the head of the bone, the handle must be raised so as to direct the point beneath the femoral vessels, lest they be wounded. The aortic compressor does not control the iliac vein, and should the femoral vein be punctured above its

part of the thigh from the trochanters to the lower end, where the skin over the patella is included in the anterior flap.

In some instances in which the tissues at the posterior part of the thigh are much diseased or injured, whilst those on the anterior aspect of the limb are sound, a very good stump may be fashioned by making a long square anterior flap, and then cutting at one stroke of the knife through the soft parts at the posterior aspect of the limb, in a somewhat oblique direction from below upwards. The anterior flap, when laid down, will form the cushion at the end of the stump.

Amputation in the lower third of the thigh is sometimes undertaken for

Fig. 78.—Amputation of the Thigh: Flaps cut from without inwards.

spontaneous gangrene of the foot. In such cases the best method is to divide the soft parts on the front of the thigh circularly down to the bone at the level of the upper border of the patella. A very short posterior skin flap is raised, and the soft parts are reflected for at least the length of the diameter of the limb before sawing the bone. Scarcely any interference with the vascular supply of the part is thus caused.

Amputation through the Trochanters may sometimes be advantageously practised, either in severe compound fractures of the lower part of the thigh, or in cases of non-malignant tumours of the lower and middle thirds of the femur; and thus the more severe and dangerous operation of disarticulation at the hip may be avoided. Indeed, should it be found, after section of the bone, that it is so much injured or diseased as to require removal at the joint,

this may readily enough be done by dissecting the head out of the acetabulum with a strong scalpel or bistoury.

Results.—The mortality after amputation of the thigh is very considerable when the operation is done for injury, more particularly for compound fracture of the femur itself. The mortality in the older statistics (p. 89) amounted to 50·7 per cent. In the more recent statistics of University College Hospital it is 46·1 per cent. Shock and traumatic gangrene of the stump are the chief causes of death.

The result of amputation of the thigh for disease of the knee-joint depends entirely upon whether the affection is acute or chronic. In acute suppurative disorganisation of the knee, amputation of the thigh is most fatal: indeed, so high is the rate of mortality, that it is doubtful whether it is proper to perform the operation in that stage of the affection. In chronic knee-joint disease, on the other hand, the operation is most satisfactory and successful: death seldom resulting unless the operation has been deferred too long. Max Schede's statistics, in which complicated cases are excluded, gives 63 cases with only one death. The mortality, as before stated (p. 86), increases as the trunk is approached.

AMPUTATION AT THE HIP-JOINT.—This formidable operation is of comparatively recent introduction into surgery. During the early part and middle of the last century its practicability was warmly debated in France. It was performed on animals experimentally. It was found that some patients affected with ergotism, whose lower extremities had become gangrenous, and had separated at the hip-joint, survived: and, at last, in the year 1773, the first successful amputation of the kind was performed by Perrault of St. Maurice. In the next year, the operation was done in England by Kerr of Northampton, on a girl aged 12, affected with hip-disease and lumbar abscess. The operation was unjustifiable in such a case, but the patient lived 17 days, and thus its practicability was demonstrated. Larrey performed it in 1793 for the first time for gun-shot injury: and since that time the operation has been established in surgical practice, civil as well as military. The operation was first performed successfully in England in 1812, by Browning of Plymouth, on a man whose thigh had been broken in the Peninsular war a year previously.

Amputation at the hip-joint has been performed in a variety of ways which it is not necessary to detail. The following will be described: 1. by combined circular and external vertical incisions: 2. by antero-posterior flaps: 3. by the oval method.

1. The amputation by **combined circular and external vertical incisions** is that usually known as *Furneaux Jordan's method*, although the operation, as now performed, differs in many respects from the description given by that Surgeon. The patient's body is drawn well to the edge of the table, and turned slightly on to the sound side. The thigh of that side is secured in the flexed position by two bandages: one attached to the thigh above the knee by a clove-hitch, the two ends of which are passed round the neck, and knotted under the arm of the same side; whilst the second bandage is passed round the sound thigh and secured to the leg of the table beneath the patient's head. The circulation through the limb is controlled by

Esmarch's elastic cord applied in the manner described on p. 47, or by an aortic compressor. An amputating knife of moderate length is to be chosen. The skin and subcutaneous tissues are divided circularly at the junction of the middle and lower thirds of the thigh, and after reflecting them for at least two inches, the muscles are divided circularly down to the bone. The femoral vessels and any others which can be recognized are now ligatured. A vertical incision is next made upwards along the outer side of the thigh from the circular cut to a point midway between the great trochanter and the iliac crest (Fig. 79). The muscles, with or without the periosteum, are turned off the shaft of the femur, and the head is turned out of the acetabulum by dividing the capsule on to the neck of the bone, whilst an assistant rotates the limb according to the direction of the Surgeon. Oozing vessels may now

Fig. 79. Fournier-Jordan's Amputation at the Hip-joint.

be secured before removing the tourniquet. The raw surface is necessarily extensive, and free provision must be made for drainage.

2. Amputation at the hip by **antero-posterior flaps** is the easiest and most speedy method. It consists in making a large and thick anterior flap by transfixion, and a short posterior one from the gluteal region and back part of the thigh. In order to perform this operation properly, the patient's body must be brought well forward upon the edge of the table, so that the nates project beyond it, and be steadied by strong bandages. One of these must be passed between the sound thigh and the perineum, and attached to the upper end of the table; another should be carried across the pelvis to the lower end; and the sound limb must be tied to the leg of the table.

The Surgeon must have three assistants on whom he can rely. Assistant No. 1 takes charge of the flap, compressing the femoral vessels; and, in the absence of the abdominal compressor, on his trustworthiness the patient's life

is mainly dependent. Assistant No. 2 holds the limb: flexing it slightly on the abdomen in the first stage of the operation, whilst the anterior flap is being made: forcibly abducting, extending, and rotating it outwards during the second stage, when the Surgeon is opening the capsule of the joint: and extending and rotating inwards during the time the posterior flap is being cut. On the way in which he performs these duties the facility with which the Surgeon performs the operation is mainly dependent. To Assistant No. 3 is consigned the care of the instrument used for controlling the circulation. After the removal of the limb, Assistant No. 2 aids the Surgeon in ligaturing the arteries. These preliminaries having been arranged, and the duty of each assistant assigned to him, the operation is to be performed in the following way:

The Surgeon, standing on the left side of the limb to be removed, feels for the bony points which guide his knife, viz. the tuber ischii and the anterior

Fig. 80. - Amputation at the Hip-joint: Formation of Anterior Flap in Left Limb.

superior spine of the ilium. The knife, which must have a blade twelve inches long, is entered, and the flap made, in different ways, according to the side of the body on which the operation is performed. If it be on the *left* side, the knife should be entered about two finger's breadths below the anterior superior spine of the ilium, and carried deeply in the limb behind the vessels, directly across the joint, its point being made to issue near the tuberosity of the ischium well behind the prominent ridge formed by the tendon of the adductor longus (Fig. 80). In transfixing on this side, care must be taken not to wound the scrotum or the opposite thigh; the back of the knife must run parallel to Poupert's ligament, and the point must not be directed too much upwards, lest it enter the abdominal cavity. As soon as the point of the knife passes the head of the bone, the handle must be raised so as to direct the point beneath the femoral vessels, lest they be wounded. The aortic compressor does not control the iliac vein, and should the femoral vein be punctured above its

last valve, most dangerous regurgitant hæmorrhage would take place. Transfixion being accomplished, the anterior flap must be cut rapidly downwards about six or eight inches in length. The assistant who is to take charge of the flap passes both hands into the wound above the back of the knife, and grasps the femoral artery firmly between his fingers and thumbs (Fig. 82). As soon as he has thus secured the vessel, the Surgeon turns the edge of the knife forwards and completes the anterior flap. In doing this, care must be taken not to make the flap pointed. This is best done by keeping the edge of the knife turned slightly towards the bone till the point is reached at which it is to be brought out. Also, the assistant who holds the limb must take care not to extend it too soon, but to keep it flexed and slightly adducted until the

Fig. 81.—Amputation at the Hip-joint: Formation of Anterior Flap in Right Limb.

anterior flap is completely cut, and the assistant who has charge of the flap must be careful not to raise it up too much nor to squeeze it laterally in grasping the vessel. As soon as the knife is brought out, the assistant holding the vessel raises the flap upwards towards the abdomen. The limb, which has so far been raised, slightly flexed and adducted, must now be forcibly extended, abducted, and rotated outwards; the capsule of the joint is then to be opened by a firm cut with the point of the knife. As soon as this is done, the head of the femur starts out of the socket and the operator touches the round ligament with the point of the knife. The assistant now allows the limb to hang down, and the head of the femur becomes separated by some distance from the acetabulum, and the posterior part of the capsule is brought into view and put on the stretch. This is divided with the point of the knife, and immediately it is done the assistant puts the limb in an extended position in a line with

the body, and at the same time rotates it inwards so that the trochanter shall not catch the knife; the heel of the knife is then passed over the trochanter, and the posterior flap rapidly cut by carrying the knife downwards and backwards through the thick muscles in this situation. The posterior flap may be about four inches in length; but this must, of course, vary according to the length of the anterior flap. When the amputation is performed on the *right* side, the anterior flap is made by entering the knife just above the tuberosity of the ischium, and bringing it out two fingers' breadth below the anterior superior spine of the ilium (Fig. 81); the remaining steps of the operation being performed as in the last case. In transfixing from the inner side, if

Fig. 82. Amputation at Hip-joint: Compression of Femoral Artery in Anterior Flap.

the point of the knife be directed too much upwards, it may enter the thyroïd foramen.

In order to avoid the inconvenience caused by standing in a cramped position between the patient's thighs, many Surgeons transfix from the outer side on the right limb as well as on the left.

In consequence of the extent to which the limb that is about to be removed may have been injured, or encroached upon by disease, it is not always easy to make the anterior flap of the size or shape described. A little management on the part of the Surgeon will, however, enable him to take the requisite amount of covering from the outer or inner parts by inclining the point or the heel of the knife downwards, as the case may require; or he may make the anterior flap by dissection, instead of by transfixion.

When the femur is entire and unbroken, Assistant No. 2 uses it as a lever, bringing the lower end of it in the second stage of the operation

downwards and outwards, thus causing the head of the bone to press against the anterior part of the capsule, and to start out with a peculiar sucking noise as soon as the latter is opened. Should the bone have been fractured high up, this movement cannot be given to it and the operation is rendered somewhat more difficult. In such a case the Surgeon must grasp the upper end of the femur below the trochanters, so as to steady and push it back as he is disarticulating its head. In two of the cases in which I have amputated at the hip-joint, it has been necessary to do this—in one, in consequence of the crushing of the bone, two inches below the trochanters, by a railway accident; in the other, in consequence of its spontaneous fracture at the junction of its upper and middle thirds, in a case of rapidly growing malignant disease of the bone.

As a farther precaution against hæmorrhage the Assistant who steadies the body may press his thumb well down into the iliac fossa so as to compress the artery against the brim of the pelvis. If the tourniquet or compressor is acting efficiently there is no hæmorrhage from the posterior flap, but should the instrument be imperfectly applied there will be free hæmorrhage from the gluteal and sciatic vessels, which must be arrested by the Assistants, who should be ready to compress them with their fingers or with dry sponges, or to seize them in force-pressure forceps. The arteries may then be ligatured one by one, as the Assistant exposes them. If the other Assistant have a good hold of the femoral, the vessels in the posterior flap may be tied first; but if the femoral be insecurely held, it must be first tied. The femoral arteries, both superficial and deep, will be found to be cut long, and to project from the muscles by which they are surrounded, so as very readily to be seized by the fingers or forceps, pulled out, and ligatured. The arteries in the posterior flap and on the inner side of the joint will be found in the intermuscular septa. The flaps are to be brought together by sutures, two or three drainage-tubes of large size must be inserted, and after the dressing has been applied, a turn of a broad bandage may be passed round the abdomen, and the end brought up from behind under the stump so as to support it.

3. The **oval amputation** may be performed in the following way: The patient is placed on his sound side and the thigh of that side is secured with bandages as in the first method above described. The patient's body must be further steadied by an Assistant placed opposite the shoulders. Another Assistant takes charge of the thigh, and a third, who stands opposite the Surgeon, will take the vessel by thrusting the fingers of one hand into the wound and grasping the artery between them and his thumb. The patient being thus prepared, and the india-rubber band or aortic compressor applied, the Surgeon stands so as to have his left hand to the flaps, that is to say, behind for the right thigh, and in front for the left. An amputating knife of moderate length is to be chosen. The incision is commenced about two inches above the trochanter and carried firmly down to the bone and along the femur to about six or seven inches below the upper end of the bone. At this point the incision is made to bifurcate, one part being carried in a curved direction forwards for about two inches and the other backwards in the same way (Fig. 83, *b*). This marks the point at which the transverse part of the incision is to be made. The limb is now abducted, and, if the first incision has been made with sufficient firmness, the operator will be able to push his thumb into the longitudinal slit which has been made in the lower parts of

the two smaller glutei. The muscles thus being put on the stretch by the Surgeon's thumb, the point of the knife is made to cut over the trochanter and down the upper part of the bone, separating the muscles attached to it, first in front and then behind. The limb is then forcibly adducted, and the Assistant at the same time tries to lift the head of the femur out by putting one of his hands on the inner side of the thigh as high up as possible. The operator then opens the joint by making a firm cut in the line of the superficial incision, so as to make a vertical slit in the capsule and divide the cotyloid ligament, and thus to render dislocation more easy. Another incision is then carried transversely through the capsule in the line of its attachment. The head of the bone then starts from the socket, and the point of the knife is inserted so as to divide the round ligament. If the head does not come out readily, the Assistant may seize the exposed trochanter with a

Fig. 56. Lines of Incision for Amputation at Hip. *a*, FORTGAIN-JORDAN'S Method; *b*, Oval Method. *c*, *d*, Upper Border of Trochanter.

pair of lion-forceps and drag it forcibly outwards. The remainder of the capsule on the inner side is then cut, and the Assistant can now lay hold of the trochanter and pull it forcibly out of the wound, and the operator, getting his knife to the inner side while he holds the soft parts out of the way with his left hand, gradually separates the bone from its attachments till it is exposed as low as is required. During this part of the operation the limb must still be adducted to the greatest possible extent. Having reached the point at which the commencement of the transverse part of the incision has already been marked, the Surgeon turns the edge of the knife away from the bone and cuts across to the inner side of the limb, thus completing the amputation. During this part of the operation the Assistant must bring the limb into a straight line with the trunk. The artery must be compressed by another Assistant with one hand in the upper part of the wound. If the limb be very muscular it is a good plan, after having enucleated the upper part of the femur, to complete the circular part of the incision by cutting from

without inwards, carrying the incision only through the skin and fat, which may then be turned up for a couple of inches, the muscles being divided last of all at the higher level. The wound must be carefully united with sutures, a large drainage-tube being inserted at the outer side.

In comparing the above methods of disarticulation at the hip-joint, that by transfixion undoubtedly has the advantage of rapidity of performance. In former times this was of the greatest importance, and the operation was often effected in from thirty to forty seconds, and frequently in even less time. With improved means of arresting hæmorrhage time is of less consequence, and the transfixion method has been largely replaced by others. The removal of the limb by circular division of the soft parts low in the thigh, and subsequent removal of the bone through a vertical incision, has very justly gained great favour of recent years; and by the adoption of this principle it may be fairly hoped that the mortality of amputation at the hip will be much diminished. The chief advantages of this method, which are only imperfectly obtained by the oval incision, are: first, that the shock is lessened by the low division of the soft parts; secondly, that the hæmorrhage may be controlled by the use of Esmarch's bandage; and thirdly, that the wound, although a very large one, is more conveniently placed for the application of an antiseptic dressing.

Results.—The mortality after amputation at the hip-joint is very high, as we should naturally expect from the size of the part removed and the consequent shock to the system. The rate of recovery varies greatly according to the condition of the limb that necessitates the operation. Thus, amputation at the hip-joint had been performed, so far as I could ascertain from published records, 126 times up to the year 1864; of these cases, 76 died. In 47 instances it was for injury: of these 35 proved fatal; whilst of 42 cases in which it was done for chronic disease, 24 recovered and only 18 died.

Primary amputation at the hip-joint in cases of severe injury of the thigh, by gunshot or otherwise, with comminution of the femur, is one of the most fatal operations in surgery.

Indeed up to the time of the American War, there was no authentic instance of recovery under these circumstances. But in the elaborate and most able surgical history of that great war, published by the Surgeon-General, 19 cases of primary amputation at the hip-joint for gunshot injury of the femur are related. Of these 11 died from the immediate shock of the operation; 5 died between the 2nd and the 10th day; and 3 recovered. One of these, a man 28 years of age, on whom the operation was performed by Surgeon Shippen, seven hours after the receipt of his wound, was in perfect health in 1892, 29 years afterwards.

Intermediate operations, or those done during the inflammatory period, are very unsuccessful: 18 cases that occurred in the American war were all fatal.

Secondary amputation, in cases of attempted preservation of the limb after severe injuries and gunshot-wounds, has been far more successful. Four cases in which J. Roux practised it in the French campaign of 1859 in Italy all recovered, as did two out of nine in which it was practised in America.

Re-amputation at the hip-joint for diseased thigh-stumps has also been a successful operation: 4 out of 7 American cases recovered.

Max Schede has collected 55 cases of amputation for injury in civil practice with 39 deaths, or 70·90 per cent.

Luning's carefully collected statistics of amputations for gunshot wounds show the following results: primary amputations—90 cases, 84 deaths, or 93·33 per cent.; intermediate amputations (from second to fourth day)—22 cases, 21 deaths, or 95·45 per cent.; secondary or late amputations—53 cases, 42 deaths, or 79·24 per cent.; amputations in which the date is not stated—65 cases, 60 deaths, or 92·30 per cent.

Amputation at the hip-joint for disease of the femur has undoubtedly become less fatal of late years than formerly. This is owing to the operation being performed at an earlier stage of the disease; to a better selection of cases; possibly to improved methods of after-treatment; but mainly to the influence of anesthetics, and the control of hæmorrhage by the use of the aortic compressor and elastic band. Max Schede's statistics give 159 cases with a mortality of 65, or 42·68 per cent.

CHAPTER IV.

LOCAL DISTURBANCES OF CIRCULATION AND
INFLAMMATION.

THE regulation of the local supply of blood to the various parts of the body is accomplished by the smaller arteries, in which the muscular coat is highly developed. When contracted a small artery may completely exclude the blood from the area it supplies, but when fully dilated it admits blood enough to distend every capillary in connection with it. These variations are controlled by the vaso-motor nerves. That stimulation of the sympathetic nerves causes contraction of the muscular coats of the arteries to which they are distributed, and that division of those nerves causes dilatation, has long been known, and there is reason to believe that in addition to these vaso-constrictor nerves, vaso-dilator nerves also exist the stimulation of which causes a dilatation of the vessels to which they pass. All vaso-motor nerves are derived originally from centres in the cord and medulla. Vaso-motor centres are distributed throughout the whole length of the cord, from which fibres pass by the anterior roots either directly to the arteries or else by the rami communicantes to the sympathetic ganglia, and are then distributed to the vessels. The vaso-motor centres in the cord are brought into connection by means of fibres passing upwards in the lateral columns with a general vaso-motor centre in the upper part of the medulla. Stimulation of this centre causes a general contraction of the vessels throughout the body, and consequently an increase of resistance and an elevation of the blood-pressure; paralysis of the centre causes an opposite effect. Cortical centres influencing the circulation have also been discovered in the motor area and in the gyrus fornicatus. The former of these, if stimulated, causes an effect on the opposite side only, while the latter produces a general effect, probably through the general centre in the medulla. Lastly, it is believed that microscopic ganglia exist on the vessels themselves, for if a part be completely separated by division of its nerves from the centres, the vessels which are at first paralysed gradually recover their tone more or less completely.

The veins possess a certain degree of tone as well as the arteries, and this is under a similar nervous control.

Variations in the calibre of the vessels may be produced, first, by direct action on the vessels themselves, as by heat, cold or injury; and secondly, by the action of the centres in the cord, medulla or brain. The action of the centres may be called into play or inhibited directly, as by injury, or by the quantity or quality of the blood circulating through them, or by the action of drugs; or indirectly by afferent stimuli. Thus the circulation of venous blood through the centres, as in asphyxia, or an insufficient quantity, as in profuse hæmorrhage, causes at first a stimulation of the general vaso-motor centre and a contraction of the vessels. Afferent stimuli act locally or

generally. Thus an emotional stimulus may cause dilatation of the vessels of the face, as in blushing; or pallor, as in fear. Stimulation of a sensory nerve, especially if prolonged and severe, causes dilatation of the vessels in the area supplied by it. Still more violent afferent impulses may lead to a general relaxation of the vessels throughout the body by temporarily paralysing the general vaso-motor centre, and this is supposed to form an important element in the condition known as shock after injury.

This brief sketch of the mechanism by which the circulation is regulated generally and locally is sufficient to show how complex the processes are by which local anemia and hyperemia are induced, and how impossible it is, in the present state of our knowledge, fully to explain all these variations in the supply of blood.

The local circulation is also influenced to a great degree by the condition of the heart. Any disease impairing its force predisposes to passive congestion or anemia of distant parts of the body.

The **Local disturbances of the circulation** are of three kinds: Local Anemia; Active Hyperemia, Active Congestion, Fluxion or Determination of Blood; and Passive Hyperemia or Passive Congestion.

LOCAL ANEMIA.

Local Anemia may be complete and permanent, as in obliteration of the arteries leading to a part by coagula, by disease of their coats, by pressure from without, or from a wound. Complete anemia may result also from diffused pressure acting on the capillaries. This condition necessarily leads to the death of the part, and will be considered when treating of gangrene. Anemia may also be incomplete and permanent from the same causes acting in a less degree. Whenever from any cause the arteries leading to a part are permanently diminished in calibre, the amount of blood circulating through the area supplied by them must be diminished, and the tissues suffer in proportion to the diminution. Such a condition is very common in old people from degenerative changes in the arteries. Under such circumstances the nutrition is impaired. If the part be external, as, for example, a limb, it is colder than natural; the growth of the epithelium is imperfect, and the surface is often dry and scaly; the nails are brittle and grow slowly; the muscles are weak and are liable to irregular painful contractions or cramp. The power of resistance to external injuries is lessened: a slight degree of cold causes gangrene; wounds tend to slough; ulceration occurs readily in the skin from superficial abrasions; and inflammation arises from causes which would fail to produce it in a healthy part, as the feeble tissues are unable to offer sufficient resistance to invading pathogenic organisms or to withstand the irritating effects of the products of putrefaction. Permanent local anemia acts therefore as a most important predisposing cause of inflammation.

Temporary local anemia may be produced intentionally by the Surgeon, as in the bloodless method of operating already described, or by pressure applied to arrest bleeding. Direct stimulation of the muscular coat of the artery, as by mechanical violence or cold or a certain degree of heat, may cause a temporary anemia. The same condition may result from reflex causes. As familiar examples of temporary local anemia, we may take the dead-white colour of fingers or toes from exposure to cold

and the anæmia of the brain with insensibility, which occurs in the condition known as concussion after a blow on the head. In the affection known as Raynaud's disease, a vaso-motor spasm occurs in symmetrical areas, most commonly the fingers, toes or ears, causing complete anæmia of the part, sometimes of such duration as to end in gangrene. Local anæmia of one part may also result from hyperæmia of another, as the amount of blood in the body is not nearly sufficient to distend all the vessels fully. An example of this is the faintness, from anæmia of the brain, which results from immersing the body in a hot bath, by which the whole of the cutaneous vessels become widely dilated, thus more or less draining the internal parts. In whatever way temporary local anæmia is produced, it ceases as soon as the cause is removed, and is replaced by hyperæmia, varying in intensity with the duration and degree of the previous anæmia. Familiar examples of this are: the red glow that succeeds when the fingers recover after having been "dead" with cold, and the blush and oozing of blood that follow the removal of the tourniquet in bloodless methods of operating.

ACTIVE LOCAL HYPERÆMIA, ACTIVE CONGESTION, DETERMINATION OF BLOOD OR FLUXION.

Active Congestion is an increased flow of blood to a part, owing to a dilatation of the arteries from relaxation of their muscular coat. Determination of blood is often very transitory, and frequently occurs as a normal process when, for temporary purposes, an increased supply of blood is called for by a particular organ.

Causes.—An increased local supply of blood is intimately associated with most surgical processes. The separation of dead parts, the repair of wounds and the healing of ulcers cannot take place without it. Every vascular tissue is susceptible of it; and in active processes in non-vascular tissues it occurs in the nearest vessels. The Surgeon often excites it intentionally as one of the most efficient of his therapeutic means. Under some circumstances, therefore, it can scarcely be considered a morbid condition. It is, however, frequently associated with disease, forming as it does an essential part of all inflammatory processes.

Hyperæmia always follows temporary anæmia of a part, as from cold or pressure, and the contraction of the vessels that occurs on stimulation of the sympathetic is likewise followed after a longer or shorter interval by relaxation with active congestion. Arterial dilatation is often reflex: thus the irritation of a sensory nerve usually causes immediate dilatation of the vessels in the area supplied by it. Another marked example of reflex hyperæmia is the engorgement of the kidney that often follows operations upon the urethra, and may terminate fatally. An irritant applied directly to a part may cause dilatation of the vessels in two ways: first, in a reflex manner by acting on the sensory nerves of the part; and, secondly, by acting injuriously on the arteries themselves, and paralysing their muscular coats. Thus, a blister when first applied causes redness by acting on the sensory nerves; but after it has been on some time, its action extends sufficiently deeply to exert a directly injurious influence on the vessels themselves. This latter condition is a part of true inflammation. Hyperæmia always accompanies the exercise of function; it occurs in glands during secretion, in muscles during exertion, &c. To this class of causes may also be referred the various forms of normal determination,

such as erection, or the enlargement of the mammary vessels during pregnancy. Lastly, anæmia of one part may be associated with hyperæmia of another, contraction of the arteries in the one causing a reflex dilatation of the vessels of the other. Thus exposure of the surface to cold may cause hyperæmia of the lungs, intestines, or kidneys.

Symptoms.—The symptoms of determination of blood, as seen in an external part, are those that we should expect to result from an increased quantity of blood rushing with increased velocity through the affected textures. They are as follows: Redness of a bright scarlet hue, swelling or rather fulness of the part from turgescence of the vessels, heat appreciable to the Surgeon's hand as well as to the patient's own sensations, a feeling of tension and throbbing, with an increase in the quantity of the secretions of the part.

Effects.—The effects of simple hyperæmia can rarely be studied uncomplicated by other conditions. It may, however, be broadly stated, that so long as the walls of the vessel are healthy, mere increased flow of blood causes no evil consequences in the affected area. In all cases in which it is the result of local irritation, it is complicated by a greater or less degree of true inflammation. In cases of hyperæmia from pressure upon the sympathetic in the neck, there is some fulness of the face but no actual œdema, and in many cases profuse sweating of the affected side of the face occurs. It gives rise to no tendency to capillary hæmorrhage, provided the vessels are healthy; but long-continued or frequently repeated determination of blood causes permanent dilatation of the capillaries and some thickening of their walls. In glandular organs active hyperæmia causes an excessive flow of secretion. Thus constantly repeated hyperæmia of the genital organs from the sexual impulses of youth not uncommonly give rise to a slight increase in the secretion of the prostate and urethra which is often a cause of needless and morbid anxiety. Occasionally it may cause hypertrophy; thus, the skin may assume a warty appearance from hypertrophy of its papillæ in the hyperæmic area round an ulcer, and sometimes there may be an excessive growth of hair from the same cause.

PASSIVE CONGESTION.

Passive Congestion or **Passive Hyperæmia** plays an important part in pathology; it gives rise to serious structural changes, and acts as a powerful predisposing cause of inflammation. It consists in accumulation of blood in the affected part from interference with its free return towards the heart. The blood in the affected area is not only greatly increased in quantity, but it circulates languidly, and, from its prolonged stay in the capillaries, it becomes more completely deoxidised than natural, and is consequently of a darker colour. The arteries are, at most, of their normal size, or even may be contracted, while the veins and capillaries are distended. When the circulation in the congested part becomes completely arrested, *stagnation* is said to occur.

Causes.—The causes of passive hyperæmia may be grouped under the following heads:—1. Diminution or loss of any of the natural forces engaged in maintaining the circulation; 2. Abnormal resistance, *a*, in the veins, *b*, in the capillaries, and *c*, in the arteries; 3. The force of gravity.

1. The three great forces concerned in maintaining the circulation are, the force of the heart, the aspiratory force of respiration, and muscular contrac-

tions in the limbs driving the blood along the veins in the direction determined by the arrangement of the valves. Extreme weakness of the heart's action is a common cause of passive congestion, its propulsive power not being sufficient to overcome the normal resistance in the capillaries, which consequently become gorged with blood. Thus we see congestion of the extremities in exhausting fevers, and the same condition readily occurs in old people. The diminution of the aspiratory force of respiration seldom plays an important part in the causation of passive congestion, but it no doubt aids in the production of those passive congestions of the viscera so commonly met with in patients dying gradually of exhausting diseases. The coldness and congestion of paralysed limbs furnish a good example of passive hyperæmia due to failure of the third force above mentioned. Passive congestion from this cause however more commonly arises from incompetence of the valves of the veins—a condition met with in all cases of varicose dilatation. When the valves are no longer competent, pressure upon a part of a vein will drive the contained blood backwards towards the capillaries, almost as readily as forwards towards the heart.

2. *Increased resistance to the flow of blood (a) through the veins* is the most common cause and produces the most typical form of passive congestion. The cause of obstruction may be inside or outside the vein, the former being such conditions as pressure of tumours, or of fæces on the pelvic veins, partial strangulation (as in hernia), &c.; and the latter, coagulation of blood in the vein, with or without inflammation of its coats, as in white leg after labour.

(b) *Increased resistance in the capillaries* and smaller veins of such a kind as to give rise to congestion is met with as a consequence of altered vital relations between the walls of the vessels and the contained blood, of such a kind that the corpuscles show an unnatural tendency to adhere and thus retard the blood-stream. This is an essential feature of inflammation, and will be described with that process.

(c) *Increased resistance in the arteries* is a common cause of passive hyperæmia. Thus, in old people, the arteries of the legs are frequently narrowed by degenerative changes in their coats to such an extent that, although allowing sufficient blood to pass to fill the vessels beyond, the force of the heart is almost completely expended before the blood reaches the veins, and thus partial stagnation, with accumulation in the capillaries, takes place. The most extreme congestion is also met with when a small terminal artery, i.e. one whose branches have no anastomosis with neighbouring arteries, suddenly becomes plugged by an embolus; that is to say, by a solid body, such as a clot washed into it by the blood-stream. As an immediate effect of the obliteration of the vessel the area supplied by it becomes more or less completely bloodless, but before long it is found to be gorged with blood. This process of hæmorrhagic infarction, as it is termed, occurs in the lung, spleen, and kidney. According to Cohnheim, the blood which distends the vessels in the congested area enters by regurgitation from the surrounding capillaries and veins. These infarcts are always found in the superficial parts of the affected organs, and Latton, in opposition to Cohnheim's view, maintains that the blood finds its way into the anæmic area from the small arteries of the pleura in the lung, or of the capsule in the spleen or kidney, and not by regurgitation from surrounding vessels.

A somewhat similar condition of intense passive congestion is very frequently

met with by the Surgeon in undermined portions of skin which have been deprived of their direct arterial supply by destruction of the subcutaneous tissue, as in phlegmonous erysipelas or superficial strumous abscesses. The thus undermined skin thus produced may hover between life and death for months, delaying healing indefinitely, and at last requiring destruction before a cure can be obtained.

3. The force of gravity plays an important part in many cases as a cause of passive congestion, especially in the pelvic viscera, the veins of which are unprovided with valves. Its effects are, however, even more marked in the leg when, as the result of disease, the valves have become incompetent. Under these circumstances the increased pressure leads to dilatation of the veins and capillaries, and consequently retards the flow of blood through them. This condition is termed *hypostatic congestion*. The most familiar examples are congestion of the legs from continued standing, and of the posterior part of the lungs of those who have been long confined to a recumbent position.

Any of the above causes may act singly or in combination with others.

Effects.—These are of much surgical importance. The first change that usually takes place is transudation of the more watery constituents of the blood into the surrounding tissues. Hence the spaces of the areolar tissue are distended by the effused fluid, giving rise to the condition known as *œdema*.

If the turgidity of the vessels be great, and especially if their walls be unhealthy, rupture will occur, and hæmorrhage from the surface or into the substance of the part will ensue. Observations made on the frog's foot after ligation of the main vein show, however, that in moderately intense congestion, the red corpuscles pass through the walls of the capillaries into the surrounding tissues, without any apparent rupture, by a process of diapedesis. This may occur with the passage of very few white corpuscles provided the vessels are healthy. The red corpuscles that thus escape from the vessels break up and are absorbed, but some of the altered blood-pigment remains behind and causes the grey pigmentation of mucous membranes or the brown colouring of the skin, which is so characteristic of repeated or long-continued congestion.

Induration from the growth of fibroid tissue, chiefly around the distended vessels, is an almost constant effect of repeated or long-continued passive congestion. But although the affected part may be increased in bulk, the normal tissue is atrophied from the pressure of the new growth. Perhaps the best illustration of this process is afforded by the *nutmeg liver* that is frequently found associated with obstructive disease of the heart. It may be said briefly that the two most marked *post-mortem* signs of prolonged or repeated passive congestion are pigmentation and induration.

The most important effect, however, of passive hyperæmia is the lowering of the vitality of the affected part, rendering it prone to inflame or ulcerate from slight causes. In congestion, although the part contains a great excess of blood at any given time, this is not changed with sufficient frequency, and consequently the amount that circulates is really less than natural.

Symptoms.—Passive congestion of an external part may be readily recognised by the changes it induces in the colour, the size, the feel, the temperature, and the functions of the part. The colour ranges from dark red to bluish purple, but if the affected part has been exposed frequently to pre-

vious attacks of congestion, it may be darkly pigmented and brown in colour; it is increased in size; if the congestion is recent and acute, it is soft from oedema, and pits under the pressure of the finger; if it is old and chronic, the tissues are indurated and brawny. The patient is conscious of a heavy, dull, aching sensation, scarcely amounting to pain, but yet attended with uneasiness. The temperature is never above, but often below, the normal standard, and the functions are lessened in activity.

The existence of congestion in an internal organ may be ascertained by finding its size increased and its functions modified, with a sensation of weight in it. The symptoms are often, however, very obscure.

Treatment.—No treatment of passive congestion can be completely successful unless the cause can be removed. The first indication consists in the removal of any source of obstruction to the return of blood from the part, as by loosening a tight bandage, or elevating a part that has been too long dependent. If the congestion be due to the feeble action of the heart, stimulants and digitalis may be of service in relieving it.

The next indication consists in lessening the quantity of blood in the congested part. The mere removal of the obstructing cause may effect this; but the desired effect is often hastened by the direct removal of blood by scarification, or by the application of leeches. The over-distended vessels may in some cases be relieved by promoting a free secretion from the part, as by the administration of purgatives for portal congestion. In some parts, again, the judicious application of pressure by means of a bandage will prevent or relieve congestion by limiting oedema and by compressing the dilated vessels, and so causing the blood to flow more rapidly through them, provided the pressure be not sufficiently powerful to interfere with the current through the arteries. With this view elastic pressure is applied to support varicose veins in the leg, and to diminish the mechanical hyperæmia of the skin that usually accompanies them.

The third indication in the treatment of congestion consists in stimulating contraction of the dilated vessels by the direct application of an astringent to them; thus we apply nitrate of silver to congested mucous membranes, and cold douches to many external forms of passive hyperæmia.

STRANGULATION.

Strangulation is the obstruction of the circulation caused by a narrow circle of pressure acting both upon the arteries and veins, as when a tight bandage is applied round a limb. Strangulation may be at once complete, the circulation through both arteries and veins being simultaneously arrested, as by the application of the tourniquet. The circulation below the band is at once arrested, but no visible changes occur in the part, nor would they do so till gangrene and decomposition commenced. In cases in which strangulation is accidental or pathological it is more commonly incomplete at first; the obstruction acts first on the veins, owing to the lower blood-pressure within them, the flow through the arteries continuing. As a consequence of this the phenomena of passive congestion appear in their most intense form; the parts below the constriction are gorged with blood, purple or black in colour, and become cold and numb. There is great swelling, and often abundant escape of red corpuscles from the vessels, or rupture of the capillaries with extrava-

sation of blood. As the part swells the constriction becomes tighter, the obstruction to the arterial flow increases, till finally the circulation is completely arrested and gangrene sets in.

ACUTE INFLAMMATION.

The study of the process of inflammation is one of the most important upon which the Surgeon can enter, for not only does it give him an insight into the greater part of the Science of Surgery, but the treatment of inflammation, as it affects the different tissues and organs, forms an essential part of his duties. However interesting the theory of inflammation may be, it is impossible to discuss it here otherwise than in outline; to gain a fuller acquaintance with it the works on general pathology and the writings of those who have made it a subject of special investigation must be consulted.

The scientific study of inflammation may be said to date from the publication of John Hunter's celebrated "Treatise on the Blood, Inflammation and Gun-shot Wounds." His knowledge was, however, necessarily limited by his not having at command the means of observing the process in the living tissues of animals. As soon as the improvements in the microscope rendered this mode of investigation possible it was actively prosecuted in this country by C. J. B. Williams, Addison and Travers, Waller, Wharton Jones and Paget, all of whom made important additions to our knowledge. Hunter, and most of his more immediate followers, regarded inflammation as a process in which the normal acts of nutrition were, although altered and perverted, more active than in health. Paget, on the other hand, had observed and accurately described the degenerative changes to be observed in tissues affected by acute inflammation. In 1858, Lister, continuing this line of observation, arrived at the conclusion that the essential feature of the acute inflammatory process is a more or less complete suspension of functional activity in the affected tissues as a consequence of some injurious influence acting upon them. This theory being, however, difficult to reconcile with the "Cellular Pathology" of Virchow, in so far as that system referred to inflammation, met with but little favour till after the rediscovery by Cohnheim in 1867 of the migration of the white corpuscles of the blood from the vessels during inflammation, a process by which the appearance of new cells in an acutely inflamed area was fully accounted for, without the necessity of supposing any increased activity, either nutritive or formative, in the original tissues of the part during the early stages of the process. Burdon-Sanderson, therefore, in 1870, defined inflammation thus: "Inflammation is the succession of changes which occurs in a living tissue when it is injured, provided that the injury is not of such a degree as at once to destroy its structure and vitality."

During the last few years, Metchnikoff, and many others who have followed him, have added much to our knowledge of the process by a comparative study of the effects of injury and disease in all forms of animal life from the amoeba upwards.

In the study of inflammation it is most important to bear in mind that the process is always the result of some injurious influence acting on the living tissue, and if the cause be removed the process will cease. It is not a disease in itself; it is in fact in most cases, if not in all, the defensive reaction of the tissue against the injurious influence acting upon them. The new cells that

invade the inflamed area are engaged in removing the portions of tissue which may have perished from the injury, or in combating the micro-organisms which may have invaded the affected area, or should the process be due to the action of a chemical irritant, the abundant exudation from the vessels tends to dilute or wash away the irritating material, and thus to bring the process to an end.

Our knowledge of inflammation has been largely derived from observation of the process artificially induced in some transparent tissue of a living animal. The web of the foot and the mesentery of the frog, and the tongue of the toad have been chiefly made use of. In order to prove that the processes observed in the frog are identical with those that occur in mammals under similar circumstances, the wing of the bat was used by Paget, and subsequently the mesentery of the rabbit was successfully experimented on. Lastly, Hueter, by observations made on the mucous membrane of the lip, showed that the processes in man are identical with those that occur in the lower animals. Microscopic examination of prepared specimens of inflamed human tissues also shows appearances which are readily explained by what is seen to take place during actual observation of the process of inflammation in the frog.

If the web of a frog's foot be spread out and examined with the microscope, the blood is seen to flow in a continuous stream through the small arteries, capillaries and veins. In any vessel which is of sufficient size to allow several corpuscles to pass at the same time, the red corpuscles flow in the centre of the stream, forming a yellow line, while on each side of this is a colourless zone, free from red corpuscles, known as the inert or plasmatic layer. In the inert layer is seen an occasional colourless corpuscle, passing somewhat lazily along, with some tendency to adhere to the wall of the vessel. If from any cause the stream be slow enough to allow of the individual red corpuscles being observed, it will be seen that they show no tendency to adhere to each other or to the wall of the vessel: although, as every one knows, when removed from the influence of the living vessels they show a remarkable degree of adhesiveness, sticking not only to each other but to every solid body with which they come in contact. The arteries show constant slight variations in calibre, which are not rhythmical, and are dependent on causes the exact nature of which is uncertain. The flow through the capillaries varies in rapidity with the state of the arteries, being more rapid when they are dilated and slower when they are contracted. In observing the foot of the frog, there will also be seen a beautiful system of branched cells containing pigment-granules, by means of which the animal is able to change the tint of its skin. When the pigment is collected into a closely packed mass round the nucleus of the cell, the frog is pale; when it is diffused evenly throughout the whole cell, the animal becomes of a darker tint. These variations of tint occur under the influence of light, the frog becoming pale when exposed to bright light and dark under the opposite condition. Thus, then, in the healthy web, there are three phenomena of easy observation, which indicate the vital activity of the tissues—the want of adhesiveness of the corpuscles, the variations in the calibre of the artery and the movement of the pigment cells. There is yet another sign of health which is not to be observed with equal ease, and that is that the capillaries allow no more serum to exude through their walls than is necessary for the healthy nutrition of the surrounding tissues, and the amount is such that any excess can be readily drained away by the lymphatics.

Supposing now that some irritating substance be applied to the web, the

normal phenomena just described will be disturbed proportionately to the potency of the irritant employed, or, in other words, to the degree of injury done to the tissues, provided that the injury is not sufficient to cause the immediate death of the tissues. The immediate effect is, in most cases, a *dilatation of the arteries*, with an *increased flow of blood to the area injured*. This is spoken of as **determination of blood to the part,—active hyperæmia,—active congestion—or fluxion**. Some irritants, such as ammonia or mechanical violence, cause *contraction* which precedes the dilatation, but this is always of brief continuance and of but little importance. The widening of the artery allows a greater quantity of blood to flow into the capillaries, which consequently become dilated in their turn. Many which in the contracted state contained no corpuscles, and were consequently invisible, now become apparent as the increased blood stream enters them, and thus new vessels seem to start into existence. The flow through the capillaries is at the same time accelerated. After a short time the dilatation extends to the vein. It would seem at first sight that dilatations of the channels through which the blood is flowing would lead to a slackening of the current rather than to increased rapidity of flow; and so it would, if the dilatation occurred equally in arteries, capillaries and veins,—but this is not the case. The small arteries are capable of very great variations in size, sometimes contracting almost to obliteration and again expanding to many times their ordinary calibre. The capillaries, on the other hand, are capable of proportionally much less dilatation, and such widening as does take place is purely passive and a consequence of the increased pressure caused by the relaxation of the arteries. The artery in a dilated state will admit to the capillaries it supplies many times the quantity of blood it allows to pass when contracted, but the combined sectional area of the capillaries is increased only by a fractional part. It is evident, therefore, that the rapidity of the flow must be increased.

The cause of the arterial dilatation is twofold. It has been shown by experiment that irritation of a sensory nerve causes dilatation of the arteries in the whole area supplied by that nerve. This is a purely reflex phenomenon. Part therefore of the dilatation is due to this cause, and is not accurately limited to the area injured. In the damaged area itself, however, the dilatation is chiefly due to the direct effect produced upon the vessels of the part by the injury that has caused the disturbance; here the muscular tissue of the small arteries is paralysed. That this is so is further shown by the fact that the degree of the dilatation is fixed and uniform, all those variations before mentioned as occurring in health being absent.

If the irritant applied to the web of the frog's foot be more powerful, it will be difficult to observe either the stage of contraction, supposing it to occur, or the stage of dilatation with increased rapidity of flow, for before the microscope can be brought to bear on the web the circulation will have undergone a third change. The vessel will be dilated as widely as possible, but the *flow of blood, instead of being increased in rapidity, will be retarded or even arrested*. In order to observe the development of this state of the circulation with greater accuracy the mesentery of the frog may be made use of, and no further irritation than exposure to the air should be applied. In a mesentery, properly prepared and protected from needless sources of irritation, the retardation of the blood-stream may be delayed for many hours. Coinci-

dently with the first signs of retardation of the blood-stream, a change is observed in the relation of the corpuscles to each other and to the walls of the vessels. They no longer flow freely and separately onwards, but show an adhesiveness not observed before, in consequence of which they tend to stick to each other and to the wall of the vessel through which they are passing. Even in health the colourless corpuscles show some degree of adhesiveness and are to be seen rolling along the wall of the vessel in the inert layer. It is not surprising, therefore, that the first signs of increased adhesiveness are noticed in the white corpuscles, which fall out of the axial stream more and more and adhere to the walls of the vessels, while the red continue to pass onwards. Thus, after a short time, a great increase of colourless corpuscles is observed in the vessels of the inflamed area; and in the small veins, in which the force of the circulation is least, they soon form a uniform layer, almost like an epithelium, adhering to the inner coat of the vessel. They are, as it were, filtered out of the passing blood, the red moving on whilst they remain behind. After a short time, as the vitality of the mesentery fails, the red corpuscles also begin to be arrested in their passage through the vessels, first in the veins and capillaries, and finally in the arteries. In the capillaries, owing to the small size of the vessels, which mostly allow only a single line of corpuscles to pass, the separation of the colourless corpuscles from the red cannot take place, and here we find the red and white mixed together. In the small arteries the first sign of retardation is that a few corpuscles stick to the inner coat during diastole of the heart, and are driven on at the next systole; and thus the stream, which in health is uniform in the more minute arteries, becomes pulsating. As the vitality of the part sinks still lower the accumulation of corpuscles increases till the vessels become choked; the red corpuscles forming, in the frog, a yellowish mass in which the individual cells cannot be recognised. All circulation is thus arrested—a condition known as “**stasis**.” Immediately before stasis becomes complete a slight movement forward may be noticed with each systole of the heart, followed by a return of the corpuscles to their former situation during diastole, an appearance to which the name of “**oscillation**” is given. The time occupied in the development of complete stasis is entirely dependent on the nature of the injury which causes it. It may be induced instantaneously by the application of any strong irritant to the web of a frog’s foot; while, in a carefully tended mesentery, its advent may be delayed for a whole day or even longer. It is evident that stasis involves a complete arrest of nutrition, which must, unless relieved, inevitably end in the death of the affected tissues before long. Should this occur, the plasma which still remains in small quantity amongst the closely packed corpuscles coagulates, and stasis becomes converted into **thrombosis**; that is to say, plugging of vessels with coagulated blood. On the other hand, should the tissues not be injured beyond recovery, the condition of stasis gradually passes off: at first some oscillatory movement is noticed; then a few of the corpuscles at the margins begin to break away into the blood-stream, and finally they all seem to lose the tendency to stick to each other or to the vessel, and move off, and the circulation gradually resumes its normal character.

The retarded flow and stasis are degrees of the same condition, and it remains now to consider the causes which bring it about. In the healthy state of the circulation, as before stated, the corpuscles show no tendency to

adhere to each other or to the walls of the vessels through which they are flowing ; on the other hand, both red and white corpuscles show a very considerable degree of adhesiveness when removed from the body. In sticking to each other and to the walls of the vessels, they are therefore behaving in the living body as if they were in contact with dead matter ; and the conclusion derived from this is, that in the healthy living tissues there are forces at work, of the nature of which we are ignorant, which counteract the natural adhesiveness of the corpuscles : but that when the vitality of a part is lowered by damage of any kind, this power is diminished or lost, according to the degree of injury the tissues have suffered, and consequently the natural adhesiveness of the corpuscles comes into play, causing increased resistance to the flow through the vessels and a corresponding degree of retardation of the blood-stream. The accumulation of the white corpuscles is explained by the fact that they possess a greater degree of adhesiveness than the red ; their form also favours their adhesion to the sides of the vessels. That the change is not in the corpuscles themselves, nor in the plasma, is shown by the fact that, if an irritant be applied to a very small area, so that a corpuscle can be watched through it, it will be seen that the adhesiveness shows itself only while the corpuscle is in the affected area : the moment it passes beyond it, it moves freely on as before. That the retardation of the flow is not the cause of the adhesion of the corpuscles is shown by the fact that, if a ligature be placed tightly round the limb of the frog so as to arrest circulation entirely, no adhesion of the corpuscles to each other or to the vessels is observed till the tissues begin to lose their vitality—a condition which, in the frog, will not come on for twenty-four hours. Cohnheim attributes all the phenomena of inflammation in the first place to molecular changes, accompanied by loss of vitality, in the walls of the vessels ; and probably in many cases of inflammation in which the source of irritation is carried to the part by the vessels their walls suffer first. No doubt also, if the vessels could escape in the case of a local injury, such as the application of mustard to the web of a frog's foot, the vascular phenomena of inflammation could not occur. But it is impossible, even in imagination, to separate the tissues from the capillaries in vascular parts ; and whether the source of damage comes from without or from within the vessels, if it is of sufficient power to cause inflammation, the surrounding tissues practically must suffer with the vessels. In the experiments on the frog's foot, Lister showed that the movements of the pigment in the branched cells ceased whenever the flow in the vessels was retarded, proving that they suffered equally with the vessels from the effects of the irritant.

Having thus traced the changes that can be readily observed in the circulation of an inflamed part, we must now turn our attention to **the processes observed in the surrounding tissues and in the walls of the vessels themselves.** For this purpose the web of the frog's foot is not well suited ; the mesentery of the frog or the tongue of the toad is more convenient for observation. Supposing the mesentery to have been exposed and prepared for examination, the first effect observed will be the dilatation of the vessels ; but if proper precautions be taken, the vitality of the part will not for two or more hours be sufficiently lowered by simple exposure to the air to cause retardation of the flow. By the application of an irritant, it might be induced instantaneously, but this would needlessly confuse the experiment. As soon as retardation sets in, the accumulation of corpuscles takes place as before described.

If a small vein in which the white corpuscles have arranged themselves along its walls be now watched, the following phenomena will be observed. An individual corpuscle being chosen and carefully watched, a small button-like projection will be seen to rise from the outer wall of the vessel, opposite the point to which it is adhering; this gradually increases in size till it becomes a hemispherical prominence corresponding in width to the remainder of the corpuscle within the lumen of the vein. As the external part increases, that inside the vessel is seen to diminish till the greater part comes to lie outside. It then assumes the form of a pear-shaped body attached to the vein by a stalk, which finally gives way, and the corpuscle is free outside the vessel. When the process of migration is completed, the contour of the vessel remains unchanged, no visible rupture of its coats being observable. The migrated

Fig. 84.—Migration of the Leucocytes, from a small vein. *w*, Wall of vessel. *l*, Leucocyte layer on inner side of the vessel wall. 1, 2, 3, and 4, Leucocytes in different stages of migration. *r*, Red blood corpuscles (axial stream).

corpuscle is irregular in shape, can be seen to shoot out delicate processes in various directions, which are drawn in again, and thus it moves farther and farther away from the vessel in which it formerly lay. From the close resemblance of these changes of form to those observed in the amoeba, they have received the name of "amoeboid movements." The whole process is known as **migration of the white corpuscles**. Fig. 84, which was drawn from life by Horsley, beautifully illustrates the process of migration. It shows the appearances in the mesentery of a frog which had been exposed for seven hours. The circulation was vigorous in the direction indicated by the arrow. At the commencement of observation there was scarcely a leucocyte outside the vessel wall. One hour and a half after there were about three times the number represented in the drawing, the excess having been omitted for the sake of clearness. The corpuscles, 1, 2, 3, and 4 in and on the wall of the

vessel, are consecutive forms assumed by one corpuscle which was watched through the wall of the small vein. The outlines of the red corpuscles are indicated for the sake of clearness, but the current was too rapid during life to admit of their being seen as drawn.

As long ago as 1841, C. J. B. Williams pointed out the fact that the white corpuscles are present in augmented numbers in the vessels of an inflamed part; but it was Addison, who, in the same year, first described their migration from the vessels. This observation was confirmed by Augustus Waller in 1846; but its importance was not recognised even by those who had observed it, and it was in fact generally doubted, till Cohnheim in 1867, published an accurate account of the process, and pointed out its bearing on the pathology of inflammation.

As a result of this process of migration of the corpuscles, the tissues of an inflamed part soon become crowded with wandering leucocytes, which may accumulate in such numbers as to conceal the normal structures more or less completely. As the inflammatory process becomes more intense, red corpuscles also leave the vessels, finding their way out chiefly from the capillaries, in the same way as has already been described as occurring in mechanical hyperæmia. The number that escape will depend very much on the degree of obstruction caused by the choking of the capillaries by adherent corpuscles. The migrating cells were at one time supposed to find their way out by natural openings or "stomata," which were believed to exist in the walls of the capillaries between the single layer of endothelial cells, of which these vessels are composed. Although no definite openings are now supposed to exist, yet it is probable that the migrating corpuscles do pass out between the cells, the natural adhesion of which to each other is lessened by those changes in the vascular walls which form an essential part of the inflammatory process. The force that causes the escape of the corpuscles differs in the case of the red and white respectively. The red are forced out by the intra-vascular pressure only, being themselves entirely passive. The white corpuscles make their way out by their own amoeboid movements, aided by the pressure within the vessels. The latter force is doubtless of great importance, for ligature of the main artery leading to the inflamed area diminishes or even arrests the process of migration. The observations of Leber, Metchnikoff, and many others have lately tended to show that the passage of the corpuscles from the vessels and their subsequent movements in the tissues are very largely influenced by the various chemical substances which may be present in the fluids of the inflamed part. These substances are in a very great proportion of all acute inflammations the products of the growth of the micro-organisms which are the immediate cause of the process. Much evidence has been brought forward to prove that the protoplasm of the leucocyte is influenced by some substances in such a way as not only to stimulate its movements but to determine them in such a direction that the corpuscle moves towards the attractive substance. Other substances produce the opposite effect and repel the corpuscles. This action of chemical substances upon motile cells of all kinds, whether animal or vegetable, has received the name of *chemotaxis*, the process of attraction being called *positive*, and that of repulsion *negative*, chemotaxis. The extreme advocates of the theory of chemotaxis are inclined to look upon it as the sole cause of migration and to maintain that the corpuscles only leave the vessels

under the stimulating influence of some positively chemiotactic substance attracting them from without, the condition of the vessel-wall being a matter of minor importance. But it is well known that migration is the immediate effect of all injuries, whether mechanical, physical, or chemical, which damage the tissues to such an extent as temporarily to suspend their activity without actually destroying their vitality. No better example of this can be given than Cohnheim's experiment of simply excluding the blood from the ear of a rabbit for a sufficient length of time to cause a distinct impairment of vitality. On readmitting the blood abundant migration takes place. It is easy to say that during the exclusion of blood bacteria have invaded the tissues or that the tissues have themselves produced a positively chemiotactic substance, but there is no proof that anything of the kind takes place, and there is no reason at present to abandon the view that a damaged condition of the walls of the vessels is a most important factor in the process of migration. It seems equally certain that migration cannot take place in the presence of a chemical substance which arrests the amoeboid movements of the corpuscles, whatever may be the condition of the walls of the vessels. It is clear also that the same substance in a high degree of concentration may arrest migration, while in a lower degree it may stimulate the movements of the corpuscles. While accepting therefore chemiotaxis as an established fact, there seems no reason to regard it as more than one of the factors concerned in the process of migration.

With the migration of the corpuscles occurs another process of equal importance—the escape of an abundant liquid exudation. It has before been stated (see Congestion) that an increase of the intravascular pressure, such as is produced by any obstruction to the return of blood through the veins, causes an abundant liquid exudation from the distended vessels. While the vessels themselves are healthy they continue to act as filters to the fluid passing through, and the effused liquid contains but little albumen, with a large proportion of salts, and is not spontaneously coagulable. In inflammation, the power of filtration is diminished, till in the higher degrees the damaged vessels allow the plasma to pass through almost if not absolutely unchanged. Inflammatory exudation is therefore much richer in albumen than the simple transudation from pressure, and is spontaneously coagulable. Its ready coagulability is due not only to its containing a larger proportion of fibrinogen, but to the presence in it of the white corpuscles which contain the other element necessary for coagulation—the “fibrin-ferment.” As this exudation takes place into tissues, the vitality of which is lowered by the damage done to them by the cause of the inflammation to such a degree that they are behaving for the time being as dead matter, all the essentials for coagulation are present, and the inflammatory effusion tends to coagulate in the affected area. In the process of coagulation some of the migrated white corpuscles break up, yielding their ferment to form the coagulum; but a vast number remain unchanged entangled in the meshes of the fibrin. The coagulated exudation contracts, just as the ordinary blood-clot does out of the body, and the serum finds its way by the lymphatics back into the circulation. The remaining clot, entangling in its meshes the wandering leucocytes, forms the so-called **inflammatory lymph**, which distends the spaces of the tissue into which the exudation has taken place. The formation of this inflammatory lymph is limited to the area of inflammation, for any of the effused plasma

which seaks beyond the area into the surrounding healthy tissues, will no longer tend to coagulate, but will drain off by the lymphatics and return to the circulation. The same will happen with any migrating corpuscles which wander beyond the area of inflammation. If the exudation is very abundant, the lymph-spaces for some distance round the centre of inflammation will be distended with fluid, and thus is produced the oedema which accompanies all acute inflammatory processes. The amount of exudation from an inflamed part is very considerable. Experiments have shown that the amount of lymph returned through the main lymphatic trunk of the thigh of a dog after inflammation has been excited in the paw, is many times the normal quantity, about one ounce escaping for every drachm that could be collected before the inflammation had been set up.

The Migrated Corpuscles in the Tissues.—We have seen in the foregoing description of the intravascular changes in inflammation that both red and white corpuscles and probably also the blood tablets may pass through the walls of the vessels into the surrounding tissues. The red corpuscles take no part in any pathological process outside the vessels. Their escape is merely an accident, and they are soon absorbed by other cells. Of the blood tablets outside the vessels we know nothing.

It is now known that the blood contains more than one form of colourless corpuscle—how many is not determined. Microscopically two chief varieties are easily recognized, one having a single large round or oval nucleus surrounded by a comparatively small amount of protoplasm, and the other having a lobed or more commonly a completely divided nucleus consisting of three or four parts surrounded by a larger amount of protoplasm. The breaking up of the nucleus has been looked upon by many pathologists rather as a sign of degeneration than of activity, for the reason that it is always found in pus-cells which are evidently dead. It seems, however, that this explanation is erroneous, for not only are the multinucleated leucocytes abundantly present in the blood, but they form at least three quarters of the migrating cells and are the most active when they have left the vessels. Metchnikoff states that the division of the nucleus greatly facilitates the passage of the corpuscle through the vessel-wall. The first function of the escaped leucocytes is to *take part in the coagulation of the exuded plasma*. A certain number of the corpuscles break up, yielding the fibrin-ferment necessary for coagulation, while the rest remain entangled in the meshes of the fibrin. As before mentioned, this forms the so-called *inflammatory lymph*. There can be little doubt that the corpuscles which thus break up are of a different variety from those that remain unchanged. Secondly, the migrated leucocytes move towards the damaged area, and invade it until the original tissues may be scarcely recognisable amongst the crowd of invading cells. This movement towards the damaged area has been explained by supposing that the damaged tissues, being in a state of suspended activity, offer less resistance than the surrounding healthy parts, and that the corpuscles therefore move in the direction of least resistance. On the other hand, the theory of attraction or chemiotaxis (p. 161) is now adopted by a large number of pathologists. It is quite evident that this movement towards the damaged area will be arrested, should the air be impregnated with any chemical substance which is capable of slowing the amoeboid corpuscles, or of destroying their vitality. In considering the movements of the leucocytes, it must be remembered that

the flow of lymph is from the inflamed area, while the movement of the corpuscles is towards it, a fact which gives considerable support to the attraction theory.

When the migrated cells have thus infiltrated the area which has been injured by the noxious agent that has caused the inflammation, it is generally accepted as a fact that under favourable circumstances they penetrate and consume any portions of tissue which may have been actually killed, thus as it were scavenging the injured area, and preparing the way for repair. The least complicated example of this is seen in the simple traumatic inflammation that occurs in a healthy incised wound during the first few hours after its infliction. Here the leucocytes have but little to do and are undisturbed by the presence of micro-organisms and their products.

The great majority of acute inflammations are, however, caused by the invasion of the affected part by micro-organisms and by the soaking of their chemical products into the surrounding tissues. Under these circumstances the leucocytes invading the affected area are found to have taken the organisms into their substance just as they do cinnabar and other foreign bodies in the blood. About this fact there is no difference of opinion, but the explanation of it has given rise to much discussion, and may still be said to be a subject of dispute.

On the one hand, Metchnikoff and his followers regard the leucocytes as the defenders of the body from the attacks of the invading microbes. They explain the process of inflammation thus. Supposing a micro-organism to have effected a lodgment in the tissues of an animal, certain chemical substances are produced by its growth which become diffused in the surrounding tissues. In some cases these products are of such a nature as to arrest the movements of the leucocytes, or even to repel them (negative chemiotaxis), and under these circumstances no migration takes place, and the invasion of the micro-organism goes on undisturbed, leading frequently to the death of the animal. In other cases the products of the growth of the micro-organism exert an attractive influence on the white corpuscles (positive chemiotaxis), and thus cause abundant migration and infiltration of the affected area with leucocytes. The leucocytes on arriving at the affected area seize on the invading organisms, taking them into their substance, as an amoeba does its prey, and destroying them by a process of intracellular digestion, thus bringing the process of invasion to an end, and curing the disease. Again, it is maintained that the products of the growth of the invading organism when diluted at some distance from the centre of invasion, attract the leucocytes by positive chemiotaxis. The migrating corpuscles moving towards the centre of infection are gradually exposed to a more intense action of the chemical substance, and their movements are arrested and finally they perish, becoming pus-cells.

This process of eating up dead tissues or invading organisms has received the name of *phagocytosis*, and the cells possessing the power of so doing are called *phagocytes*. It will be seen subsequently that many other cells can act as phagocytes besides the white corpuscles, but in all probability during the acute stage of inflammation, when the original tissues of this part are suffering from the damage done by the cause of this process, the leucocytes are the only cells capable of actively exerting their phagocytic properties.

Metchnikoff regards the process of phagocytosis as the essence of inflammation.

tion—so much so that he says “the essential and primordial element of a typical inflammation consists in a reaction of phagocytes against a noxious agent.” This view may be correct as regards inflammation caused by an invading organism, but the simplest and most typical inflammation is that caused by mechanical violence, and here the process of cell emigration and exudation can hardly be regarded as defensive, as it does not take place till after the noxious agent has ceased to act. To regard the phagocytic action of leucocytes and other cells as the whole of inflammation seems to be taking too narrow a view of the process.

In opposition to Metchnikoff, Buchner and many others are of opinion that the amoeboid cells merely take into their substance organisms which are already dead, and while granting to the fullest extent the scavenging powers of the migrated cells, they deny their defensive action against invading organisms.

Metchnikoff supports his views by a comparative study of the behaviour of motile cells under injury in all classes of animals, from the unicellular organisms to mammalia, and brings forward a large amount of evidence in favour of his views. The whole subject of phagocytosis as a defensive process will be considered again in the Chapter on Infective Diseases.

Lastly, the leucocytes have been credited with the function of taking part in the formation of new tissue. Within a few years of Cohnheim's re-discovery of the migration of the colourless corpuscles this view was almost universally accepted. All the latest observations, however, tend to the opposite view, and the opinion most generally held now is that after having served their purpose as scavengers or as the first line of defence against invading organisms, they are themselves absorbed by other phagocytes derived from the original tissues, or pass back into the lymph stream. Whether migrated leucocytes can proliferate after leaving the vessels is also a disputed point, and one which must at present be considered as unsettled.

The Tissues.—The effect of inflammation on the tissues of the affected part has been the subject of much discussion, and cannot yet be said to be finally settled. It was shown by Lister, in 1858, that in the area exposed to the action of an irritant every indication of life is in abeyance during the most acute stage of the resulting inflammation. The muscular coats of the arteries cease to show the irregular contractions seen in health, the pigment-cells in a frog's foot no longer exhibit their peculiar changes, and the blood flowing through the part behaves as if in contact with dead matter. He thus came up to the conclusions to which his observations led him: “It appears that the various physical and chemical agents which, when operating powerfully, extinguish the life of the constituents of the animal body, produce by a somewhat gentler action a condition bordering upon loss of vitality, but quite distinct from it, in which the tissues are, for the time being, incapacitated from discharging their wonted office, though retaining the faculty of returning afterwards, by virtue of their own inherent powers, to their former state of being, provided the irritation have not been too severe or protracted.” To this may be added that a still gentler action of the same agents, short of that necessary to produce the phenomena of inflammation, may stimulate the cells of the affected part to increased activity and proliferation. This theory alone, however, inadequate to account for the appearance of a multitude of new cells in tissues still suffering from the effect of an injury, and yet the

microscope shows that this forms an essential part of acute inflammation. Consequently Lister's theory did not meet with the acceptance it deserved; and until the migration of the white corpuscles was finally established by Cohnheim in 1867, the process of inflammation, according to the Cellular Pathology of Virchow, was regarded as essentially one of increased nutritive and formative activity of the inflamed tissues. All the new cells were supposed to be formed by the rapid proliferation of the original elements of the affected tissues. The discovery of the migration of the white corpuscles, however, fully accounted for the appearance of the new cells in the inflamed area, without necessitating the improbable assumption, that injury to living tissues immediately increases their vital activity.

The changes which occur in the tissues as the result of inflammation have been observed both in vascular and non-vascular structures, during life and in preparations made after death. Amongst non-vascular structures the cornea may be taken as the type, and has most frequently been made the subject of investigation. The cornea is composed of a peculiar form of fibrous tissue arranged in strata, between which lie spaces of an irregular stellate form containing corpuscles corresponding with them in shape but not accurately filling them, thus leaving room for the passage of blood plasma and, under certain conditions, of white corpuscles. When the cornea of any animal is irritated by passing a fine silk thread through it, there forms, before many hours are past, an opaque spot extending for a short distance round the part injured. At the same time the vessels of the conjunctiva and of the sclerotic become engorged with blood. If the cornea be cut out and examined about sixteen to twenty-four hours after the injury, in the inflamed area, instead of the single stellate corpuscle naturally seen in each space, there will be found a group of rounded cells having all the appearances of white corpuscles. At one time it was thought that these were produced by proliferation of the corneal corpuscles. It has since been shown clearly that the appearance is really due to an accumulation of migrating cells in the space in which the corneal corpuscle lies, so as more or less completely to obscure the original cell. Whenever the original cell can be recognised, it shows no change. The behaviour of the corneal corpuscles under the influence of irritants was made the subject of a careful investigation by Seuffleben. He applied to an extremely limited area in the centre of the cornea a solution of chloride of zinc of sufficient strength to kill the corpuscles with which it came directly in contact, without apparently damaging the fibrous tissue and especially the anterior homogeneous lamina. This was not followed by any dilatation of the peri-corneal vessels, and no cloudiness appeared round the injured area. The microscope showed no alteration in the uninjured corpuscles surrounding the damaged area and no migration of leucocytes into it. The explanation of this is that from the very small amount of the caustic applied, if any found its way by the lymph channels to the neighbourhood of the peri-corneal vessels, it arrived there so greatly diluted as not to produce any injurious effect on them, and thus no dilatation or migration took place. If the anterior homogeneous lamina was accidentally destroyed, the damaged tissue beneath, being exposed to the air, became septic, and the products of the septic change reaching the peri-corneal vessels damaged them, causing dilatation and migration into the cornea. The same effect could be produced by using a larger amount of the caustic or by applying it too near the corneal margin. Seuffleben showed, therefore, that

unless the irritant act directly on the vessels surrounding the cornea no new cells appear in the damaged area, and nothing resembling proliferation of the corneal corpuscles takes place. His experiments further showed that about two days after the caustic had been applied, the corpuscles next to those which have been actually killed recover from the minor degree of injury to which they had been exposed, and commence to repair the damaged area. This is accomplished by spear-like processes of protoplasm which shoot out from the cells into the damaged area. A nucleus appears at the end of the process, the protoplasm surrounding it increases in quantity, and by a repetition of this process the loss of substance is repaired, the dead cells being absorbed by the advancing new growth. Nothing was observed to justify the belief that the corneal corpuscles under any circumstances divide and subdivide, thus forming a group of small round cells resembling a collection of migrated leucocytes. The importance of these observations on the question of repair is evident.

The observations of Semple have been fully confirmed by Leber in his exhaustive work on inflammation, published in 1891. Leber found that a species of *aspergillus*, the *aspergillus fumigatus*, when inoculated on the cornea grew readily, the mycelium of the fungus forcing its ways amongst the layers of the tissue. The effects of the growth of the fungus may be briefly summed up as follows: the inoculation having been made in the centre of the cornea, by the third day the part actually invaded by the fungus is evidently dead, forming an opaque spot around the seat of inoculation, and the margin of the cornea near the sclerotic vessels is cloudy. A day or two later three zones can be recognised: in the centre is the opaque spot formed by the dead corneal tissue invaded by the fungus; round this is a clear ring; and round this again a slightly elevated, yellowish-white opaque ring sharply defined towards the clear zone before mentioned, and gradually merging into the somewhat cloudy cornea between it and the sclerotic. In the next stage the yellow ring breaks down into pus, and the dead portion of the cornea with the fungus is cast off. At the same time inflammation of the conjunctiva and of the deeper structures of the eye usually took place: but this for the sake of clearness may be ignored. Microscopic examination shows the mycelium of the fungus infiltrating the corneal tissue in the opaque centre. In the transparent zone the corneal corpuscles cannot be recognised, and are evidently dead. In the ring of infiltration innumerable closely packed leucocytes conceal the corneal tissue. Leber explains the whole process thus: the fungus in its growth gives rise to an intensely irritating diffusible chemical product which kills the tissue it directly acts on: this causes the opaque necrotic spot in the centre. The transparent zone round the centre is also killed, but is not invaded by leucocytes, because it is impregnated by the chemical irritant in such a state of concentration as to repel the migrating cells. The chemical irritant becoming more dilute as it diffuses from the point of its production, by the time it reaches the vessels at the corneal margin damages them to the degree necessary to cause migration. Leber explains the movement of the corpuscles from the vessels towards the point of inoculation by the theory of chemiotaxis before mentioned (p. 161). He believes that the chemical substance generated in the centre when diluted at the margin of the cornea exerts an attractive influence on the leucocytes (positive chemiotaxis) which makes them crowd towards the damaged spot, but the same substance acting more intensely as the migrating cells approach the

centre, first arrests their movements and finally kills them, forming thus the purulent ring above mentioned.

The tongue of the toad has been examined by Dowdeswell with the object of ascertaining whether the fixed connective-tissue corpuscles take any part in the formation of the new cells which appear in inflammation. The details of his observations were published in the proceedings of the Royal Society in 1876, and he gives the following brief summary of the results he obtained: "So long as the circulation continued, no change whatever took place in the connective-tissue corpuscles, either as regards form or appearance, notwithstanding that the tissue of which they formed part was beset with innumerable emigrant colourless corpuscles, or (to use ordinary language) was infiltrated

Fig. 85.—Inflamed Fat. Showing the fat cells with leucocytes between them. The migration is most abundant near a small vessel. Large granular cells derived from fat cells are seen.

with pus." In some cases the tongue was watched for eight or even nine days.

The conclusions drawn from these observations are confirmed by the microscopic examination of specimens of other inflamed tissues. In fat the leucocytes are found crowding between the fat cells, especially in the neighbourhood of small blood-vessels (Fig. 85); in muscle they accumulate between the fibres which themselves show no change, unless the process be very acute, and then the alteration is in the direction of degeneration, not of growth (Fig. 86). In bone the Haversian canals become filled with leucocytes; and should the process be of sufficient intensity and duration, the solid tissue disappears before the new cells, while at the same time the bone-corpuscles show no change unless one of degeneration. Thus acute inflammation in its early

stages, from whatever cause, and in whatever tissue it may arise, is always characterised histologically by essentially the same phenomena: a passive or degenerating condition of the original tissues with an abundant infiltration of new cells, which are white corpuscles migrated from the vessels, and possibly, the descendants of such corpuscles formed by division of the parent-cells after leaving the vessel.

The extent to which the process of cell-infiltration is carried depends upon the degree of damage done to the tissues by the irritant which has caused the inflammation. Supposing the damage done to be of a slight and temporary character, the tissues speedily recover from the condition of lowered vitality into which they have been thrown, the vessels recovering with the other parts. The circulation, therefore, returns to its normal state, and the exudation of plasma and migration of leucocytes cease. The liquid exudation drains away and such leucocytes as have found their way amongst the tissues find their way back by the lymphatics, or are absorbed by larger cells which may now appear on the scene. These larger cells also are motile and possess the properties of phagocytes, and from their size have been called *macro-phages* or large phagocytes to distinguish them from the smaller cells already described, which have received the name of *microphages* or small phagocytes. The words microphages and macrophages are untranslated French, and not adapted to the English language. It is better to use the terms *micro- and macro-phagocytes* or large and small phagocytes. These larger cells are supposed to be formed by proliferation of the original cells of the part as they recover from the damage done to them by the irritant.

It has before been pointed out that the same cause which, acting intensely, will cause the phenomena of inflammation, may in a milder form act as a stimulus to the tissues, causing increased nutritive activity and proliferation, just as the same chemical substance in a high degree of concentration arrests the movements of amoeboid cells, while in a lower degree it stimulates their activity. It will be seen later on that, in chronic inflammations due to irritants of low intensity, cells of this type are abundantly present in all stages of the process. The sources of these larger phagocytes are supposed to be the connective-tissue corpuscles and the endothelial cells of the vessels and epithelia.

It is possible that some of the larger cells may be formed by fusion of the smaller. The observations of Metchnikoff have clearly shown that this process occurs in many of the lower invertebrata when resisting the invasion of foreign organisms. Nothing of the kind appears to take place in acute

Fig. 86. *f*. Fascia, arteriosclerotic and slightly infiltrated with leucocytes. *a*. Arteriole. *v*. Vein. *p*. Perimyosium infiltrated with leucocytes. *n*. Nerve. *m*. Muscular fibres, cut across.

inflammation in the higher animals, but possibly the giant cells found in many forms of chronic inflammation may have their origin in this way.

The observations of Ballance and Sherrington, which will again be referred to in the Chapter on Wounds, confirm the above views. They showed that during the stage of traumatic inflammation resulting from a wound leucocytes (small phagocytes) appeared only in the injured area, and it was not till the inflammation had subsided, some eighteen hours after the infliction of the wound, that the large mobile cells (large phagocytes) made their appearance.

The functions of these larger cells are as follows. First, they complete the scavenging process which the leucocytes had commenced. The evidence of this is that they are frequently found enclosing in their substance fragments of tissue, red corpuscles, and micro-organisms, either dead or alive; and lastly the leucocytes, having performed their allotted duty, become as it were foreign bodies. Secondly, there seems to be no reason to doubt that these larger cells, derived from the original tissue of the part, are the active elements of repair in those cases in which the inflammatory process has been associated with actual destruction of tissue. As before stated, the latest observations tend more and more conclusively to prove that the migrated leucocytes take no part in the formation of new tissue.

The sequence of events in acute inflammation not accompanied by the formation of pus would therefore seem to be this:—The original cause of the process, the irritant, damages the tissues, temporarily suspending their vital activity, and possibly actually killing portions here and there. While the tissues are in this inert state they are invaded by the migrating leucocytes which, under favourable circumstances, proceed to remove any dead tissues, and perform the other functions above described. As the tissues recover, the original cell elements proliferate, and the cells thus formed also acting as phagocytes, complete the scavenging of the damaged area, consuming such migrated leucocytes as have not wandered away by the lymphatics, and then undertake the repair of the damaged tissues if necessary.

This process of recovery from inflammation, and restoration of the tissues to their normal condition without apparent change, is described as the termination of inflammation by resolution with *restitutio ad integrum*. The formation of scar-tissue in the place of any of the original tissues that may have perished will be described more fully in the Chapter on Repair.

Should the damage be more extensive, and of such severity that a small portion of the tissue is directly killed or injured to such a degree that the pressure of the accumulating cells and liquid exudation extinguishes such traces of vitality as may be left in it, it is evident that the simple process of resolution is impossible. The same will be the case when the cause of the inflammation is of a more persistent character, especially when the tissues are invaded by certain micro-organisms to be described in the Chapter on Suppuration. Under these circumstances, the exudation from the vessels and the migration of the leucocytes continue in the inflamed area until the leucocytes become heaped up and packed together amongst the damaged tissues, which now show signs of degeneration. The fibres of the connective tissue become swollen and softened, and finally disappear amongst the leucocytes; fat cells lose their contents, and in like manner are lost amongst the invading cells; muscular fibres lose their striation and become granular; the migrating cells penetrate within the sarcolemma, and the original tissue disappears before them; the

vessels in the same way become obliterated by pressure and are lost in the mass of new cells. In whatever part or tissue the change may be occurring the process is essentially the same—the original tissues degenerate and disintegrate, and their place is taken by a closely packed crowd of migrated leucocytes. Even at this stage it is possible for the process to stop should the cause of irritation cease to act. The leucocytes would then be removed in the way above described, the new cells derived from the original tissues would occupy the space, and recovery would take place with the formation of scar-tissue in the damaged area which would remain permanently through life.

Should the cause continue to act, the process will culminate in the formation of pus or suppuration. This condition is brought about by the softening of the intercellular substance in the centre of the group of closely packed leucocytes. The migrated cells themselves are cut off from proper nutrition by their mutual pressure, and are exposed to the injurious action of the micro-organisms which are almost invariably present in all cases of acute suppuration, and they consequently undergo degenerative changes and finally perish. They assume a more circular form: their protoplasm becomes filled with large highly refracting granules, some of which are fatty and soluble in ether, while others are albumenoid and can be cleared up by acetic acid. When thus cleared the cell, which now receives the name of a **pus-cell**, is found to contain a double or triple or sometimes quadruple nucleus. This was at one time considered a sign of degeneration, but, as before stated (p. 163), the greater number of the migrating leucocytes in their most active stage contain a similar multiple nucleus. The fluid which separates the pus-cells is formed partly by the softening of the intercellular substance which separated the heaped up leucocytes, and partly by the liquid exudation from the surrounding inflamed tissues soaking in amongst them. With this fluid come fresh wandering leucocytes; so that in the fluid drawn from an acute collection of pus, not only are the round dead pus-cells found, but with them many still showing faintly granular protoplasm and ameboid movements of the white blood corpuscle. The nature of pus, and the process by which a small collection spreads and forms an abscess, will be further discussed under Suppuration and Abscess.

If the process that has just been described should occur on a surface so that the pus finds a ready escape as soon as it is formed, we get another result of inflammation, which receives the name of **Ulceration**. The process of ulceration is, indeed, identical with that of the formation of a localised collection of pus. The original tissues are infiltrated by migrating cells which gradually destroy them and fill the space they formerly occupied; the new cells in their turn degenerate on the surface and are cast off as pus-cells. This will be further considered under Ulceration.

Inflammation has also been described as terminating in gangrene. This is most frequently the effect of some micro-organism invading the tissues, and going on in its growth to chemical products of so intensely irritating a character as to cause the death of the tissues upon which they act. At some distance from the invaded area the diluted products give rise to the phenomena of inflammation, but as the invading organisms advance the more concentrated ones kill the tissues. Another way in which the inflammatory process may end in gangrene is the arrest of the circulation by the pressure of the exuda-

tion. This is especially apt to occur when the circulation is feeble from partial obliteration, as the arteries from disease. It is also seen in frost-bite. Here the part is practically bloodless while frozen, but on being thawed becomes at once flooded with blood. If the tissues have been damaged to the degree necessary to give rise to inflammatory exudation, the pressure of the exudate, combined with the increased resistance from the retarded flow in the vessels, arrests the circulation, and the part which at first seemed likely to recover may become gangrenous (see Chapter XXX).

From the above description of the process of inflammation, it will be seen that the essential features are the retarded flow in the vessels, and the exudation of cells and plasma. The simple hyperæmia that occurs as the result of milder degrees of irritation cannot be looked upon as constituting a part of the true inflammation; and, on the other hand, when the stage of stasis is reached, inflammation must soon be brought to an end by the death of the affected part, unless the circulation be restored by the subsidence of the process. The process of acute inflammation is identical in all cases; it may vary in degree, in extent, and in termination according to the nature of the cause, and the vitality of the tissues on which the cause is acting, but the process is always the same. When, therefore, varieties of inflammation are spoken of, it must be borne in mind that the variations do not depend on differences in the essential nature of the process, in so far as the changes within the vessels and the exudation are concerned, but are the result of variations in the cause, and in the degree to which the vessels and other tissues are damaged by it.

CAUSES OF INFLAMMATION.—The causes of inflammation, like those of all other morbid processes, may be divided into **predisposing** and **exciting**.

The **Predisposing causes** may briefly be said to include every condition that tends to lower the vitality of the tissues, and thus to render them less able to resist external injurious influences. We now know that by far the most important of all external injurious influences causing inflammation is the invasion of the tissues by pathogenic micro-organisms, and it is a universal law throughout the animal and vegetable kingdom that feeble individuals most easily fall a prey to parasites of all kinds. The conditions necessary for healthy nutrition, and consequently for a high degree of vitality, are an abundant supply of healthy blood, connexion with a healthy nervous centre, periodical rest from functional activity, and at the same time a normal exercise of function. The influences disturbing these conditions may be *Local* or *General*.

Local Predisposing Causes.—The local conditions which interfere with the *quantity* of blood supplied to a part, have already been discussed under *Local Anæmia* and *Congestion*. In *Passive Congestion*, it will be remembered that, although the part habitually contains an excess of blood, there is a diminished interchange, and, consequently, the actual quantity supplied is less than natural. Both these local disturbances of circulation interfere with healthy nutrition, lower the vitality of the affected part, and thus render it prone to inflame from slight causes.

Loss of connexion with a healthy nerve-centre may be the result of destruction of the nerve-centre itself, or of injury to the nerves leading from the centre to the affected part. The best illustration of the effect of this condition is seen in contrasting paralysis of a limb from cerebral hæmorrhage, and paralysis

from acute spinal myelitis. In the former case, the paralysed limb is still in connexion with the healthy spinal cord, and ordinary care in avoiding pressure will prevent any formation of bed-sores. In the latter case, the slightest pressure or irritation causes inflammation, rapidly terminating in sloughing. Loss of connexion with a healthy nerve-centre is also seen not unfrequently in cases of division of the ulnar nerve, by which the little finger is completely cut off from its nervous supply. Under these circumstances, grave changes in nutrition are common, and inflammation is readily set up. That organs to which *insufficient rest* is given are prone to inflame, is, perhaps, best illustrated by the effects of excessive work on the eye; and the converse, that organs *cut off from the performance of their natural function* suffer in nutrition, is seen in the fact that limbs condemned to inaction from disease of a joint are cold and waste, and that inflammation is set up in them by comparatively slight causes.

Though every tissue of the body is susceptible of inflammation, yet *some parts, from their anatomical conditions and structure, are more liable to it than others*. All cavities are exposed when wounded to the dangers of the accumulation of putrid or irritating fluids, and thus the serous and synovial membranes readily become affected with extensive spreading inflammation. Mucous and cutaneous surfaces, on the other hand, are protected by a strong and thick epithelium, and consequently require more powerful causes to produce inflammation.

When a part, *having once been the seat of inflammation*, has been left in a weakened or impaired state, it is more liable to a second attack, as it has less resisting power; hence, also a subsequent attack may be induced by a less active exciting cause than that which at first started the process; we see this in the inflammatory affections of the eyes and joints.

Constitutional Predisposing Causes.—That *old age* acts as a predisposing cause of inflammation, it is hardly necessary to say, the vitality of the tissues being greatly diminished in extreme age. *Anything that enfeebles the heart's action* to such a degree as to interfere with the supply of blood to the tissues, acts as a predisposing cause of inflammation. Thus operation wounds are more prone to become inflamed after great loss of blood, and in patients weakened by long fever or want of food. For healthy nutrition, it is not only necessary that there should be an abundant supply of blood, but *the blood that is supplied must be in a healthy condition*. The blood may be rendered impure by the addition to it of some substance not normally present, or by the imperfect elimination of the products of normal tissue change, or by the deficiency of some of its normal constituents. The most common and most important of the first class of conditions, is the habitual presence in the blood of an amount of alcohol in excess of that which can be easily eliminated or consumed. This is unfortunately the constant condition of but too many of the working classes, especially in large cities. A healthy country labourer, working hard in pure air, may consume and eliminate rapidly a large amount of alcohol; but the city workman, engaged in a more or less sedentary occupation in an ill-ventilated workshop, is less able to get rid of the alcohol he takes; while at the same time, the quantity he takes is probably greater, as his wages are higher and his opportunities for drinking more abundant. There can be no doubt that this condition of chronic alcoholism exerts a most prejudicial influence on all operations and diseases of the inhabitants of large

cities. *Habitual excess in eating* is almost as injurious as excessive drinking; for, as only a certain amount of food can be properly digested and assimilated, excess above this tends to interfere with healthy nutrition.

Chronic lead-, mercury-, and phosphorus-poisoning are other examples of the same class of causes. *The absorption of the chemical products of putrefaction from a wound*, as we shall see hereafter, causes severe fever; and the rapid wasting of the body which occurs in this condition is clear evidence of the serious disturbance of nutrition that it gives rise to. It is the experience of all Surgeons that wounds made during septic fever are exceptionally liable to inflammation, and generally do badly.

Saccharine diabetes, which of all conditions exerts the most injurious influence on wounds and injuries, may perhaps be most conveniently classed under this heading; as also *jaundice* when due to simple obstruction of the bile ducts.

Amongst the causes of *impurity of blood from insufficient elimination of the normal products of tissue change*, Bright's disease is the most important. *Gout* also is perhaps most properly included under this heading. Both these conditions are powerful predisposing causes of inflammation. Diseases of the lungs and liver act in the same way.

Amongst conditions due to the *insufficiency of some of the normal constituents of the blood* is anaemia, such as is commonly seen in young women; and here also might be classed those conditions due to a deficient supply of the necessary elements of food, such as scurvy, from want of fresh, green vegetables, and the general condition of mal-nutrition brought about by deficiency of oxygen in the air habitually breathed and want of food in general.

Lastly, there is the constitutional condition known as *scrofula*, in which inflammation tends to occur under the influence of exciting causes less in degree than those which affect healthy subjects; but the essential nature of this condition is still but imperfectly known.

Exciting Causes of Inflammation.—Inflammation is usually said to be the immediate result of *local "irritation,"* and the causes of inflammation are commonly spoken of as "*irritants.*" Irritation properly means excitement (*irrito*, I excite); and consequently the physiologists speak of tissues possessing "*irritability,*" when a healthy manifestation of functional activity can be induced by the application of external stimuli. At the time when inflammation was believed to be an exaggeration of the normal activity of the inflamed tissues, the cause that produced it was very naturally spoken of as an irritant. Now that acute inflammation is known to be essentially a condition of diminished vital activity of the tissues in the inflamed area, the term may give rise to some misconception unless the sense in which it is used be clearly understood; at the same time, its use in the sense of something causing inflammation has become so firmly fixed, not only in surgical but in popular language, that it would be most inconvenient to try to change it. An irritant may, therefore, be defined as something tending to damage the tissues on which it acts, and temporarily to lower their vitality; if acting more feebly, it frequently acts as a stimulus, calling forth manifestations of normal function; if more severely or persistently, it causes the death of the tissue upon which it acts. Heat may be given as an example. If the skin be exposed to a temperature of about 100° F., simple hyperemia results with increase of normal function, as shown by perspiration; boiling water applied merely for a second causes

inflammation ; and a red hot iron would, of course, give rise to immediate death of the part it touched. The effect produced by an irritant will depend first, upon the intensity of the irritant ; and secondly, upon the powers of resistance of the tissues on which it acts : thus, in the feeble tissues of a limb the arteries of which are so diseased as to bring the supply of blood below the normal standard, inflammation is readily induced by slight causes. It has already been stated that insufficient supply of blood acts as a powerful predisposing cause of inflammation : the complete arrest of the circulation, if continued for a sufficient length of time, acts as a direct exciting cause. This was shown by Colucheim in his well-known experiments on the tongue of the frog and on the ear of the rabbit. If the ear of the rabbit be emptied of blood, and a temporary ligature applied at its base, the effect produced is proportional to the time during which the ear is kept bloodless ; if this be a few hours only, temporary hyperæmia alone results, with perhaps slight swelling ; if about twelve hours, the ear becomes greatly swollen, there is retarded flow in the vessels with abundant inflammatory exudation, and the tissues become infiltrated with migrating white blood-corpuscles ; if the ear be kept bloodless till its vitality is lost, the blood cannot enter it, the corpuscles immediately choking the vessels and blocking them as in inflammatory stasis, so that any flow is impossible. Thus any degree of inflammation can be produced at will by varying the time during which the ear is kept bloodless. Colucheim showed also that after the ear has been bloodless for a time sufficient in some degree to lower its vitality, slight injuries cause a higher degree of inflammation than in a healthy ear. This experiment is sometimes unintentionally performed on the human subject. Some years ago a patient came under my care, whose whole arm had been accidentally rendered bloodless by the application of an apparatus for the treatment of fracture of the clavicle. At first, when the bandages were removed, the limb seemed hopelessly dead ; but after a short time it was evident that, although its vitality was reduced to the lowest possible degree, it was not absolutely destroyed, for the blood began slowly to find its way even to the finger-tips, but with this all the phenomena of acute inflammation were developed. The limb became swollen, red and tense to such an extent that the circulation became again arrested by the pressure of the exudation, and gangrene set in, necessitating amputation at the shoulder-joint. On making incisions into the amputated limb, a most abundant inflammatory exudation, like thin pus, streamed from the subcutaneous tissues and muscles. The same phenomena are observed in strangulated hernia. It is a well-known fact that in complete strangulation, even when the gut has been cut off from the circulation for many hours, no inflammatory exudation is found on its surface when the sac is opened in the operation ; but should the patient die shortly after reduction, the gut is found covered with a thick layer of inflammatory exudation. Here, as in the rabbit's ear, the phenomena of inflammation do not manifest themselves till the circulation is re-established in the strangulated part.

Irritants, that is to say, injurious influences acting as causes of inflammation, may be divided into six groups : **Mechanical, Physical, Chemical, Organised, Functional, and Nervous.**

Mechanical Irritants may be thus subdivided :—(a) *Direct mechanical causes*, as in wounds, bruises, fractures of bones, &c. (b) *Movement*, which is a frequent cause of persistence of inflammation, as in inflamed joints, but is

seldom an exciting cause of the original mischief. (c) *Friction*, as in blisters on the feet and hands. (d) *Tension*. Tension acts both as a primary and a secondary cause of inflammation; a tight stitch, pent-up discharges in a wound, or obstruction of the duct of a gland, are all familiar examples of tension acting primarily as a cause of inflammation. As a secondary cause it comes into play very frequently to a greater or lesser degree, causing a persistence of the process till it is in some way relieved. The pressure of the exudation prevents the return of vitality in the parts injured by the primary cause of the inflammation, and thus delays or prevents recovery. In the treatment of inflammation we shall see that many of the means adopted have for their object the prevention of tension and pressure from excessive exudation. In an acute abscess the tension produced by the fluid takes an important part in maintaining the process of suppuration, which subsides more or less completely as soon as the pus is let out.

2. **Physical.**—Under this heading are included *heat, cold and electricity*. The effects of the two first are too familiar to require further explanation. Electricity acts as a cause of inflammation only when it gives rise to decomposition of the tissues by electrolysis.

In *gout* the local inflammation is probably usually determined by some slight injury, but the actual cause is the excess of uric acid in the blood, and urate of soda is deposited in the affected part. We have here an example of an acute inflammation caused by a chemical substance formed in the body itself. It has been shown by Gautier and others that alkaloidal substances, to which he gave the name of *leucomaines*, are formed by the decomposition of albuminous bodies during the normal metabolic processes taking place in the tissues. These bodies are poisonous, like the ptomaines formed in putrefaction, and it is possible, though there is no evidence to prove it, that the local formation and accumulation of such substances may be the cause of some inflammations apparently arising spontaneously.

3. **Chemical.**—All strong *acids and alkalis* and innumerable *salts*, such as corrosive sublimate, chloride of zinc, &c., act as irritants when applied to the tissues. Numerous *natural products of the vegetable kingdom*, such as croton oil, mustard, &c., and some *animal products*, such as cantharides and the poison of various venomous reptiles and insects, act more or less powerfully as exciting causes of inflammation.

The most important, however, of all the class of irritants in surgical practice are the chemical products of the fermentative processes set up by the growth of micro-organisms in various albuminous fluids. These processes may be divided into two great classes, first, the **simple septic processes or ordinary putrefaction**, in which the micro-organisms grow only in dead matter, such as serous fluids accumulated in a wound or portions of dead tissue, the effect on the living tissues being caused by the chemical products of putrefaction becoming diffused in them; and secondly, those more complicated processes in which the micro-organisms invade the living tissues and act as genuine parasites. It was to the irritation caused by the micro-organisms and their products that the inflammation and suppuration which formerly accompanied almost all large wounds were due, and the modern improvement in surgery is almost entirely due to our more accurate knowledge of the conditions under which micro-organisms can develop, and the means by which their growth can be prevented. It is necessary, therefore, here briefly to consider the nature and

necessary conditions of these fermentative processes, taking as the type the ordinary putrefaction of animal matter.

Decomposition or putrefaction of animal matter is a process of fermentation, the essential conditions of which are, 1, *the presence of dead animal matter*; 2, *a sufficient supply of oxygen*; 3, *the presence of water*; 4, *the maintenance of a certain temperature*; and 5, *the ferment*. These may be considered more in detail.

1. **The presence of dead animal matter.**—We have already seen that in acute inflammation a coagulable exudation takes place; when this coagulates it entangles in the meshes of the fibrin a vast number of white corpuscles which have migrated from the vessels, thus forming the so-called inflammatory lymph, while the serum either flows away by the lymphatics or accumulates in the spaces natural to the part. In the case of an open wound the exudation accumulates on the surface and forms, as will afterwards be seen, the first bond of union; while the serum drains away, unless, from any imperfection in the treatment, it is allowed to accumulate in the cavity of the wound. In compound fractures and wounds opening the natural cavities of the body, perfect drainage is not always possible. The exudation is composed to so large an extent of living cells that it may be looked upon as living tissue, and consequently incapable of undergoing putrefaction. It is otherwise with the serum, which is dead matter. Extravasated blood, either in the spaces of the areolar tissue, as in a bad bruise, or in the cavity of a wound or other injury, as in a compound fracture, is also decomposable, although less readily than the serum which is squeezed out of the clot as it contracts. The pus contained in an abscess, or the urine in a distended bladder, are other examples of putrescible animal matter in the living body.

2. **A sufficient supply of oxygen.**—The tissues themselves, and the blood circulating in them, contain quite enough oxygen for the process of putrefaction. This is shown by the fact that offensive decomposition frequently takes place in wounds from which, immediately after the injury, the air has been excluded by some external application, such as styptic colloid, collodion, or the like.

3. **The presence of water.**—All living tissues and the fluids of the body contain enough water to putrefy readily, but the proportion is not that most favourable to the process. The more watery an exudation, the more readily will it decompose.

4. **The maintenance of a certain temperature.**—Experience shows that the temperature of the human body is one highly favourable to the process of putrefaction.

5. **The presence of the ferment.**—The four previous conditions of putrefaction have been universally recognised for a long time past; but the necessity for the action of a ferment as the starting-point of the process is amongst the modern discoveries of science. Ferments are of two kinds, *organised* and *non-organised*. The *organised ferments* are microscopic vegetable organisms belonging to the class of fungi; the *non-organised* are chemical substances, such as diastase, pepsin, ptyalin, &c., which give rise to definite chemical changes in the special substance upon which they act. The process of putrefaction is a fermentation, dependent on the presence of vegetable organisms belonging to the lowest class of fungi.

In all putrefying animal fluids these organisms are found in great abund-

ance. They are very commonly spoken of collectively as "bacteria," though the name "bacterium" belongs more properly to one special form. The term **Schizomycetes** ($\sigma\chi\iota\zeta\omega$, I cleave, and $\mu\acute{\upsilon\kappa\eta\varsigma}$, a fungus), or **fission-fungi**, is employed for the whole order. The fission-fungi are divided into classes according to their forms, the chief being the Micrococci, or round organisms; Bacilli, or rod-shaped organisms; and Spirilla, or corkscrew-shaped organisms. All these organisms are composed of a mass of protoplasm, without a nucleus, enclosed in a delicate cell-wall. They multiply chiefly by fission, but some varieties grow from spores.

Micrococci are round or slightly oval organisms, varying from $\frac{1}{10000}$ to $\frac{1}{1000}$ of an inch in diameter, and are often recognisable only by the highest powers of the microscope. They occur singly or grouped in pairs (diplococcus), chains (strepto-coccus), or clusters (staphylo-coccus). When in colonies they are often bound together by a homogeneous substance termed "Zoogloea." There is no reason to believe that they ever lengthen out into rod-shaped organisms, as they can be cultivated for many generations in various media without changing their form. They are non-motile, and are reproduced chiefly by fission, but under certain circumstances some members of a colony or a whole generation are said to assume the characters of spores, at the same time undergoing little or no change in their external appearance. This would explain the persistence of the virus of some of those diseases which are supposed to be due to micrococci.

The **rod-shaped organisms** are generally divided into **bacteria** and **bacilli**. **Bacteria** are minute fungi having the form of very short cylinders with rounded ends. They are often so short that they are more correctly described as oval than as rod-shaped. They exhibit active movements, but occasionally a group become united together by a jellylike substance or zoogloea, which limits or arrests their motion. Their movements are in many varieties produced by a flagellum at one or both ends. This can only be recognised by the very highest powers of the microscope. Bacteria multiply by fission, and spore formation has not been demonstrated.

Bacilli are cylindrical in form, like bacteria, but their length is greater in proportion to their breadth. They vary greatly in size, some forms not being more than $\frac{1}{10000}$ of an inch in length, while others may reach $\frac{1}{2500}$. In form some varieties are straight, others slightly curved. They are mostly non-motile, but some kinds are provided with a flagellum and are capable of movement. All multiply by fission, and the separate segments may remain attached to each other, forming long jointed filaments. Most, if not all, also propagate themselves by spores under special conditions. The spore first appears in the substance of the bacillus as a bright spot, which gradually increases in size, consuming a certain proportion of the protoplasm in so doing, till it may form a slight thickening of the rod at the point at which it lies. Several spores commonly form in each rod. Finally, the remaining protoplasm perishes, the sheath gives way, and the spores become free. The spores stain feebly or not at all with most aniline dyes, and are thus recognised without difficulty.

The term **leptothrix** is applied to very long thread-like organisms. These are constantly present in the mouth.

Spirilla are spiral filaments, possessing active powers of movement. They are believed to form spores like bacilli. When the corkscrew-like turns are

most markedly developed the curved organism is termed a **vibrio**. This classification is extremely imperfect, but in the present state of our knowledge, neither botanists, bacteriologists, nor pathologists seem to be able to agree on any definite arrangement of these organisms. It is probable that the same organism under different conditions of growth may vary considerably in form, and this adds another difficulty in the way of accurate classification.

All these organisms being destitute of chlorophyl, consume oxygen in their growth and give off carbon dioxide. Some require free oxygen, and are for that reason termed "*aërobic*" by Pasteur; others derive their oxygen from the organic compounds in which they grow, and cannot develop in the presence of free oxygen, and are then termed "*anaërobic*;" others again are *aërobic* or *anaërobic*, according to the circumstances in which they are placed. All require an abundant supply of water, without which they cannot grow.

All these micro-organisms are killed by boiling the liquid in which they are growing, and most by a temperature of 140° F. Freezing is also fatal to many forms, and few survive prolonged drying. All chemical substances classed as antiseptics, such as carbolic acid, salicylic acid, perchloride of mercury, &c., when in solutions of sufficient strength, destroy their vitality; in weaker solutions they inhibit their growth.

The spores of the bacilli, however, exhibit the most remarkable resisting powers. They are not affected by boiling unless it be prolonged for some minutes; they are uninjured by drying or freezing, and only the most powerful antiseptic solutions will destroy their vitality. None, however, are supposed to be capable of withstanding a dry heat of 250° F. maintained for one hour.

Among these various fungi some are capable of developing in dead matter only; others can attack living tissues and grow amongst them like true parasites. The former are termed *septic organisms*, *saprophytes*, or *carriage fungi*; the latter *parasitic*, or *pathogenic fungi*. It is with the septic fungi only that we have to deal at the present moment.

Each fungus which acts as a ferment is supposed to set up a special process accompanied by the formation of definite chemical compounds, but this subject is at present very imperfectly worked out. In putrid animal fluids many forms of fungi, belonging to all the classes above mentioned—micrococci, bacteria, bacilli, vibriones and spirilla—are always met with, and the products of ordinary putrefaction are consequently extremely numerous and complex. It is impossible to name a special organism for every product, and there is no doubt that one may give rise to many. The chief products of putrefaction of animal matter are the following:—*Gases*: Nitrogen, Carburetted hydrogen, Hydrogen sulphide, Hydrogen phosphide, Ammonia, Ammonium carbonate. *Acids*: Formic, Acetic, Butyric, Propionic; Ammonium sulphide. Tyrosin and Leucin are also present. In addition to these, substances chemically allied to Alkaloids, and known as *Promaines*, are developed. Amongst the most important of these are neuridine, suprine, cadaverine and putrescine, which are almost constantly found in the putrefaction of proteids. These substances are locally irritating to the tissues, and when absorbed are intensely poisonous. Bergmann also isolated a crystalline substance, to which he gave the name of *Spavin*, and which he believed to be the special toxic agent in septic fluids; but the poisonous and irritating properties of putrid matter are not due to a single substance, and in the present state of our knowledge it is more conve-

nient to use the general term "products of putrefaction" than to attempt to specify any special septic poison.

As a general rule, it may be stated that when gas is abundantly developed in a putrid animal substance this is due to the presence of bacteria, most micrococci and bacilli not giving rise to any appreciable amount of gaseous products. In ordinary fetid putrefaction one organism constantly present is the *bacterium termo*. This is a short actively-moving organism, rather oval than rodlike in shape. It requires abundant water for its growth, and is easily destroyed by drying and by all antiseptics. When micrococci alone exist in an albuminous fluid there may be a sour smell, but there is not the ordinary fetid odour of putrefaction. In the practical prevention of fermentative changes in animal fluids, as in the antiseptic treatment of wounds, it is found much easier to exclude bacteria than micrococci, as these latter seem to grow under conditions which destroy the former.

It has been proved by experiment that septic or non-pathogenic organisms cannot develop amongst living tissues, and should they enter the blood-stream they speedily perish. The local and constitutional effects they produce are solely by means of the chemical products formed in the dead matter in which they are growing.

That these organisms are the actual cause of putrefaction of dead animal matter, and that they are derived from pre-existing organisms of the same kind, is universally acknowledged. It is impossible here to discuss the evidence by which this has been proved. So far as our present purpose is concerned, it may be sufficient to state that putrescible fluids, such as urine, milk, or hydrocele serum, if collected in vessels which have been heated to a temperature sufficient to destroy all living organisms, and with due precautions to avoid contamination from other sources, may be kept for an indefinite time without undergoing any chemical change or developing any fungoid growths. Air may be freely admitted to them without producing any sign of putrefaction if it has previously been deprived by filtration of any solid particles floating in it, or if it has been submitted to a sufficiently high temperature, or to the action of some chemical substance capable of destroying the vitality of any living organism. It is evident, therefore, that putrefaction is not merely a chemical process caused by the presence of gases of the air. If a fluid or solid cultivating medium which has thus been kept unchanged for weeks, or even months, be exposed to unpurified air for a few seconds, and then again protected, no result may follow; if for a few minutes, microscopic fungi are almost sure to make their appearance; but it is by no means certain that the organism that appears will be one of the fission-fungi, or that the fermentation that follows will be ordinary fetid putrefaction. More commonly moulds of various kinds appear, especially if the air be dry. If the exposure be prolonged, or the air very damp, the probability of the appearance of micrococci, bacteria or bacilli will be much greater. The conclusion drawn from this is that the spores of moulds are always floating in the air in considerable numbers, but that fission-fungi are much less abundant, although often present. The same result may be obtained by cultivating the dust of a room on nutritive gelatine or on a boiled potato. In a series of cultivations bacteria and micrococci appear occasionally, while the moulds constantly develop. By exposing fluids or other cultivating media to the air for fixed periods of time, it can be clearly shown that all forms of organisms exist much more abund-

any in the air of houses than in that of the open country, and more in great cities than smaller towns (see p. 8).

The number and nature of the organisms which develop after exposure of artificial cultivating media to the air have been found by Miquel to vary considerably with the composition of the fluids used. Thus, he states that a measured quantity of air containing 200 organisms capable of developing on a weak neutralised solution of Liebig's extract of meat might only contain one capable of growing in a neutralised infusion of hay. This he terms a difference of "sensitiveness" or "putrescibility." It would seem that pus, blood-serum, and more especially blood, have a low degree of putrescibility, and may be exposed to unpurified air with much less risk of decomposition than was at first supposed, the great majority of air-borne organisms being incapable of developing in albuminous fluids of so high a degree of concentration. Although by applying the results of experiments made with highly sensitive fluids directly to serum and blood an exaggerated idea of the putrescibility of these fluids was at one time entertained, it cannot be denied that organisms may be present in the air which are capable of growing and setting up fermentative changes even in those concentrated albuminous fluids, and it would seem wiser not to run into the opposite extreme of ignoring air-borne organisms altogether as a source of infection of the discharges of wounds or abscesses. In our damp climate especially it is certain that the ordinary septic bacteria are usually present in the dust of the air.

If instead of exposing the putrescible fluid to the air a small quantity of unpurified water be added, bacteria make their appearance with almost absolute certainty, and ordinary ferid putrefaction most commonly follows. From this it is to be concluded that water is the special habitat of the ordinary bacteria of putrefaction. However much, therefore, we may feel justified in relaxing some of the precautions which were at first recommended for the exclusion of the dust of the air from wounds, we cannot be too careful to avoid the use of water which has not been rendered innocuous by boiling or by the admixture of some efficient antiseptic.

It having been clearly proved therefore that these micro-organisms are the cause of the process of putrefaction, by what means can they gain access to the putrescible matter in wounds, abscesses or cavities containing animal fluids?

Only two modes of entrance need be considered: 1. *The organisms might be conceived to enter by the lungs and alimentary canal*, and thus find their way into the circulation and enter the dead matter from within. That this mode of entrance does not occur with the ordinary saprophytes or organisms of putrefaction, is evident from the fact that subcutaneous accumulations of putrescible fluids, such as pus and serum, or portions of dead tissue, such as a part of an organ cut off from its blood supply by a simple embolus, do not undergo putrefaction. It has, moreover, been shown by experiment that the fungi which cause ordinary putrefaction, even if injected into the bloodstream, speedily perish, and thus no such organisms are present in the tissues of a healthy animal. That other forms of organisms can enter in this way must be acknowledged, for in all acute infective inflammations and acute abscesses, microscopic organisms are found at the seat of disease even when there is no external wound.

2. *The bacteria are admitted directly from without.* Of this there can be no

doubt. We have already seen that they may be present in the air, although not in such numbers as was at one time supposed; they are more abundant, however, in the neighbourhood of decomposing matter, as in a ward containing many wounds the discharges of which are in a state of decomposition. They are carried into wounds, abscesses, or other cavities by the Surgeon's hands, by instruments, and more especially by water, unless some means are adopted to destroy them; and they are abundantly present in the unpurified skin of the human body. Still it cannot be too clearly understood that even when they are carried into the body, or into a wound, the ordinary bacteria of putrefaction can do no harm unless they come in contact with dead matter. They speedily perish in the blood, and they exert no influence on living tissues. Amongst living tissues we must class the coagulable lymph that covers the surface of a wound; while the serum is dead matter. In a wound or abscess cavity, therefore, which is perfectly drained, the bacteria soon perish; and were perfect drainage always possible, we need not fear their presence. This is not always possible, however; and consequently it becomes in most cases a matter of great importance to exclude all micro-organisms from wounds or abscesses, and to destroy any which may have found admission.

4. Organised Irritants or Parasites.—This class of irritants includes those organisms which have the power of growing as true parasites in the living tissues of the animal body. Among them must be included certain animal parasites, such as the itch insect (*acarus scabiei*), the chigoe (*pulex penetrans*), the trichina spiralis, &c., which bury themselves in the living tissues and there excite a greater or less degree of inflammation. These are of little importance however, compared to the vegetable organisms which are the direct cause of many forms of inflammation, as erysipelas, malignant pustule, and other specific affections. It is probable that the inflammation set up by these parasitic fungi is the result of the formation of irritating chemical products by a process analogous to putrefaction and fermentation; still it is important to make a very clear distinction between the effects of simple putrefaction and the inflammation caused by these more potent organisms. In simple putrefaction the irritating material is formed as the result of changes occurring in the dead matter only, and may be regarded as being developed outside the body; and, when it gives rise to spreading inflammation, this is due merely to the chemical products of the process soaking into the surrounding tissues, just as any soluble irritating salt, such as corrosive sublimate, might do; but the irritant does not increase in quantity amongst the living tissues, and its effects are directly proportional to the quantity developed locally. There is, in other words, no *infection* of the surrounding tissues. With the organisms of which we are now speaking, however, the case is different, for they grow into the surrounding living tissues, and excite inflammation as they spread; they enter the circulation by the lymph-stream or by the blood-vessels, and may multiply in the circulating blood, giving rise to changes in its composition incompatible with life, or they may lodge in distant parts, and there grow and set up local inflammation similar to that at the original seat of disease. From their direct power of exciting unhealthy processes, these organisms are spoken of as "*pathogenic fungi*." They cause a *true infection both locally amongst the tissues adjoining the part first affected, and generally in the whole system*. The poison multiplies in the body of the affected individual, and the effects it produces are not directly proportional to the quantity of the original

dose inoculated. To inflammations arising from this cause the term "**infective**" is applied.

The pathogenic organisms belong to the same orders and classes as the saprophytes just described. They belong chiefly to the orders micrococcus and bacillus (see p. 178), but pathogenic bacteria are also met with, as in emphysematous gangrene. The individual species will be described with the diseases with which they are associated (Anthrax, Glanders, Tubercle, Erysipelas, &c.).

The theory of infective inflammations generally received at the present time is that under certain conditions these parasitic fungi take up their abode in a part of the body frequently already damaged, as in a wound or a centre of suppuration, and then, while growing, give rise to a process of fermentation in the fluids of the part, the products of which are irritating locally, and poisonous if absorbed into the system. Some forms are capable of multiplying in the blood and thus affecting the whole system. They are then supposed to act partly by lodging in minute vessels and exciting at the point at which they are arrested a process of inflammation similar to that in the original seat of disease, partly by forming poisonous products by their action on the fluids of the blood, and partly, like true parasites, by absorbing oxygen and other nutriment to the detriment of the tissues of the body.

The **true infective inflammations** are therefore due to the accidental introduction of a poison or virus which possesses the power of increasing in quantity in the living tissues. The effect produced is, therefore, quite irrespective of the size of the original wound or starting-point of the inflammation. Thus the prick of a needle in sewing up a body after a post-mortem examination may start an inflammation extending through the whole arm. In an infective process of this kind the virus exists abundantly in the products of the inflammation, that is to say, in the inflammatory exudation, and if by any means these products are transferred from one part of the body to another, they set up a similar unhealthy inflammation wherever they may lodge; and, in like manner, a similar inflammation may be started in another individual by inoculation of the exudation. The local spread of the inflammation is due to the irritating inflammatory products which contain the ferment-like poison finding their way into the lymph-spaces of the surrounding tissues. An infective inflammation may be limited to one part of the body, and spread merely by local infection, as in spreading gangrene and phlegmonous erysipelas; or the poison may be taken up by the lymphatics, and cause inflammation similar in character to the original process in the nearest lymphatic glands without infecting the system generally, as in soft chancre and some forms of dissecting wound; or it may be carried throughout the body by means of broken-down clots from the veins of the primary seat of disease, giving rise to local inflammation wherever the fragments of clot may lodge, as in some forms of pyæmia; or lastly, the poison may enter the blood and multiply in it, giving rise to a general infective process, as in septic infection, malignant pustule (splenic fever), or syphilis. The term "infective" is, therefore, applied only to those conditions in which the poison multiplies in the living tissues of the body; when the infection merely spreads locally without affecting the whole system, the result is called a **local infective inflammation**; when the poison enters the system and multiplies throughout it, presumably in the blood, the affection is spoken of as a **general infective**

process. Before it can be accepted as proved that any organism is the actual cause of a specific form of inflammation or infective process, the following conditions laid down by Koch must be fulfilled :

1. In every case of the disease in question submitted to examination a micro-organism possessing morphological characters sufficiently definite for its recognition must be found in the affected tissues or the blood.

2. The micro-organism must be cultivated out of the body in a suitable medium in such a manner as to prevent its accidental contamination by any other organism. The cultivation must be carried on to many generations by successively inoculating fresh portions of the cultivating medium with the growth, until it may be assumed that no trace remains of the blood or other animal matter with which the first culture was necessarily contaminated.

3. The pure culture of the organism must then be inoculated in an animal susceptible to the disease in question, with the result of producing the specific affection.

4. Lastly, the characteristic organism must again be found in the tissues or blood of the animal in which the disease has been artificially induced.

All these conditions have been fulfilled in a large number of diseases of animals, such as anthrax, glanders, swine-plague, spreading gangrene in mice, &c. &c. In three diseases the two last conditions have been fulfilled in the human subject. Fehleisen has successfully inoculated the micrococcus of erysipelas, Bokai that of gonorrhœa, and Garre the staphylococcus of boils.

On the other hand, in some undoubtedly infective inflammations, as, for example, syphilis and soft chancres, no specific organism has yet been definitely proved to be the actual cause.

The action of the pathogenic fungi, the mode of invasion of the body, and the resistance offered to their attacks, will again be referred to in the chapter on infective diseases in general.

Admitting to the fullest possible extent the influence of pathogenic fungi in the causation of infective processes in wounds and elsewhere, experience teaches us that the hygienic surroundings of the patient exert an influence of the greatest importance in their development.

Putrefaction is, as we all know, a process quite independent of hygienic conditions : a dead body will become putrid in the fresh air of the country just as surely as in a crowded city, and in the same way pent-up discharges will putrefy in a palace as certainly as in the foulest dwelling of the poor. Under the best hygienic conditions, if putrid discharges accumulate in a wound or in the cavity of an opened abscess, local inflammation and suppuration are excited, and union of the wound or closing of the abscess-cavity is delayed. The local and constitutional disturbance will, however, be less than when the patient is exposed to bad hygienic conditions ; for the tissues being better nourished and of higher vitality, will suffer less from the irritation of the septic matter, and the septic poison entering the system will be more readily eliminated. True infective processes in wounds are rare, even when the discharges are decomposing, unless at the same time the patient is exposed to unhealthy surroundings. In private practice erysipelas was uncommon, pyæmia was rarely met with, and hospital gangrene unknown, even when no special means were adopted to prevent decomposition of the discharges. If, however, a number of patients whose wounds are treated

without antiseptics, be crowded together, as in the case of the wounded after a battle, even if it be in a building which has never before been used for such a purpose, infective processes are certain to manifest themselves. How it is that infective processes characterised by the presence of a specific virus capable of transference from one individual to another, make their appearance under unfavourable hygienic conditions is still far from being fully understood. It is yet to be determined whether each form of infective inflammation is due to a specific organism constantly present in the air or in water and ready to attack the patient when the unhealthy surroundings to which he is exposed, or other causes of mal-nutrition, such as prolonged wound-fever, or constitutional disease have reduced his strength so far as to make it possible for the parasitic fungi to invade his body; or whether simple, non-pathogenic organisms may, by growing in the discharge of a wound rendered unhealthy by putrefaction, develop a virulence they did not before possess, and so become capable of invading the living tissues. Koch and other observers have shown that, however the organisms may acquire their virulent properties, and whatever may be their origin, when a characteristic organism has been found associated with a distinct form of infective inflammation, it can be transferred from animal to animal by inoculation and even cultivated artificially in proper media outside the body; and that, generation after generation, it reproduces itself in the same form, and when inoculated produces the same variety of infective process. It has also been shown by Pasteur and many others that the virulence of an organism may be so reduced as almost to be lost by cultivating it in unsuitable media, or under unfavourable conditions, or by passing it through animals little susceptible to its influence, and that by opposite means its full potency may be restored to it. This fact certainly favours the second theory as to the development of pathogenic fungi.

When a specific organism has once found its way into a hospital ward, it is evident that, unless wounds be specially protected, infection of one from another may easily occur through the air, the danger being diminished proportionally to the separation of the patients and the freedom of admission of fresh air. The poison can also undoubtedly be carried from one wound to another by dirty instruments, or sponges, or by the Surgeon's hands or clothes.

Many pathogenic organisms, besides being inoculable externally, can undoubtedly enter the blood-stream by the lungs or alimentary canal, and thus the local seat of inflammation from within. Microscopic organisms are found in all acute abscesses and in many infective inflammations in which there is no open wound; and we must, therefore, admit that they have found their way in by the lungs or alimentary canal. We have before seen that this mode of entrance cannot be admitted in the case of the ordinary bacteria of decomposition; it is equally certain that it cannot be denied in the case of the organisms of infective inflammations. Experience, however, teaches that it is not by any means common in local injuries; for the total absence of organisms from a wound can be assured, almost with certainty, by means resorted to protect it from external contamination only.

Next, it remains to be discussed, what is the relation of ordinary putrefaction to the development of infective inflammations?

Ordinary putrefaction acts both generally and locally. The invasion of the living tissues by an infective process may be regarded as a struggle between

the virus and the tissues, and anything that lowers the vitality of the latter will favour the former. The putrefying discharges irritate the parts with which they come in contact and directly lower their vitality, as is evidenced by the inflammation set up; and they thus favour the invasion of the tissues by the pathogenic bacteria. This would only be in harmony with the well-known fact common to the animal and vegetable kingdoms, that feeble individuals, or feeble parts of an individual, are most readily invaded by parasitic fungi.

The contrast between a wound healing aseptically by the first intention and one in which septic suppuration is taking place on the third day is very marked. In the former case, tissues in a full state of vitality are separated merely by a thin layer of plastic exudation so largely composed of living cells that it may fairly be regarded as living tissue; in the latter, the tissues for some distance on each side are lowered in their vitality by the irritation of the products of putrefaction, and are separated from each other by a fluid which forms one of the most suitable media for the development of any true infective virus that may find admission to it.

Generally decomposition of the discharges acts in two ways: first, it depresses the patient by the fever caused by the absorption of the products of putrefaction, and thus renders him more liable to suffer from any general infective process; and secondly, it is a well-recognised fact that the emanations from putrid matter exert an injurious influence on the health of those who inhale them—in fact, the removal of putrescible matter, or the prevention of its decomposition, forms one of the most essential features of domestic and hospital hygiene.

No greater mistake could be made, however, than to imagine that with the prevention of putrefaction all necessary hygienic precautions are ended. As before pointed out (p. 9), the products of respiration foul the air and exert a depressing influence on those who breathe it to a degree that cannot be overrated; and too great attention cannot be paid to ventilation and the avoidance of overcrowding.

5. Functional Irritation.—Every tissue requires a periodic rest from functional activity for healthy nutrition, but it is very seldom that the want of such rest can act as more than a predisposing cause of inflammation. Occasionally, however, inflammations of joints or of the eyes seem to be directly dependent on excessive exercise of function.

6. Nervous Irritants.—The part played by the nervous system in the direct causation of inflammation has always been a question involved in considerable obscurity. That inflammation can take place, and readily does so, in a part completely cut off from any connection with the central nervous system has been proved by numerous experiments; in fact, such a condition has already been described as a predisposing cause of the process. The clinical phenomena usually cited as examples of inflammation arising from injurious influences transmitted to the affected part by means of the nervous system, are the so-called sympathetic inflammations of the eye and of the testicle, and herpes zoster. It is a well-known fact that, when one eye is affected by destructive inflammation following a wound, unless the diseased globe be early removed, the other eye is liable also to become inflamed. The latest observations, however, tend to prove that the inflammation in such cases in reality spreads from one eye to the other by direct extension along the

optic nerve to the commissure. Gonorrhœal inflammation of the testicle is in like manner now usually regarded as a direct extension of the inflammation by means of the vas deferens. Herpes zoster is an inflammation of the skin arising from no known external cause, and usually limited to the area supplied by a single sensory nerve or nerve-root. In this case we can scarcely doubt that the cause, whatever it may be, acts in some way through the nerve. Although it is difficult to prove that the nerves take, ordinarily, any active part in the causation of inflammation, there is no doubt they exert an important influence on its progress by their controlling influence on the circulation. Irritation of a sensory nerve is known to cause dilatation of the vessels in the whole area supplied by the nerve; and the painful stretching of the nerves in inflammatory swelling, by causing such a dilatation, increases the blood pressure in the inflamed part, and consequently augments the exudation and aggravates the tension.

Varieties of Inflammation.—John Hunter divided inflammation first into two kinds, viz. the healthy and the unhealthy. "The healthy," he says, "probably consists only of one kind, not being divisible but into its different stages." "The unhealthy admits of vast variety," "according to the kind of health in the constitution or part." He also divided inflammation according to its effects into "the adhesive, the suppurative, and the ulcerative." The term "**adhesive inflammation**" has for nearly one hundred years occupied so important a place in surgical language, that it will be better here briefly to define it. Adhesive inflammation is the result of an irritant acting temporarily with such a degree of severity as to cause exudation of almost pure blood-plasma and migration of the corpuscles, with coagulation of the fibrin in or on the injured tissues. At the same time, the damage done by the irritant must not be of such severity as to cause the death of any appreciable amount of tissue; nor must it continue to act after it has produced the degree of impaired vitality in the vessels necessary to cause the exudation. To take an example: the damage done by the passage of a sharp knife through healthy living tissues is sufficient to develop in the area acted upon the stage of inflammation characterised by retardation of the blood-stream, exudation of a coagulable fluid and migration of white corpuscles. The exudation coagulates on the injured surface and in the spaces of the injured tissue, the fibrin and the white corpuscles remain, forming what is known as "inflammatory lymph," and the serum partly drains away externally and partly returns by the lymphatics to the circulation. This inflammatory lymph is the material of adhesion in adhesive inflammation, and if two surfaces covered with it are brought in contact, they adhere to each other. The knife can of course act only while cutting the tissues; the moment the cut is made the cause ceases, the effect only remaining. If no new cause of irritation comes into play (such as the friction of the surfaces on each other, or the presence of foreign bodies, or chemical irritants as putrid matter, persistently-acting, powerful antiseptics, &c.) the effect gradually subsides, the injured tissues recover their vitality, exudation ceases, the coagulated inflammatory lymph remaining glues the surfaces to each other, and adhesive inflammation is said to have taken place. Should some persistent source of irritation, such as one of those above-mentioned, be brought into play in the wound, the exudation does not cease so long as the cause of irritation is acting; consequently, such "inflammatory lymph" as may have been formed by the coagulation of the exudation,

becomes softened by the continuous flow from the vessels, and infiltrated by innumerable migrating corpuscles till it breaks up and flows away as pus, and "**suppurative inflammation**" is said to have been developed. At the same time that this is taking place, the tissues which form the surfaces of the wound, being unable in consequence of the presence of the irritant to return to their normal state of vitality, become infiltrated by innumerable wandering cells which fill all the spaces and press upon the original tissues, finally absorbing them and occupying their place; thus the surface of the wound becomes converted into a layer of closely packed leucocytes, the superficial cells of which are continually degenerating, becoming loosened, and floating away in the discharge as pus-cells. Beneath this layer the original cells of the tissue begin to proliferate, being protected by it from the direct action of the irritant, and thus we get a new tissue developed from the old, in which new vessels develop, forming granulation tissue, the superficial cells of which, when they become exposed to the irritant, break down, and take part in the formation of pus. If, in consequence of a higher degree of irritation, the new growth from the original cells is very limited or altogether absent, and thus destruction exceeds formation, the process gradually extends into surrounding tissues: a new layer becomes infiltrated by migrating cells, pressed upon and absorbed, and its place occupied by the crowded leucocytes, which in their turn break down and are thrown off, and thus a progressive destruction of tissue takes place. This process is called **ulceration**; or, in the language of Hunter, "**ulcerative inflammation**" is said to be occurring. If the irritation be still more severe, the migrating cells may perish before they have formed a distinct layer: and, instead of the process just described, in which the original tissues are first replaced by the leucocytes, which then break down and melt away as pus, the tissues may themselves undergo direct disintegration, and the products of this change will form part of the discharge, which under these circumstances will contain shreds of the broken-down tissues and be less rich in leucocytes, or, in other words, in pus-cells. Thus in rapid ulceration the discharge may be scarcely puriform, but composed of serous fluid with the *debris* of the perishing tissues. Lastly, if the irritation be still more intense and rapid in its action, or the original vitality of the affected part so low that it is incapable of resisting even mild injurious influences, the death of the original tissue will take place with such rapidity that the dead mass will be visible to the naked eye, forming a **slough**, and the process is then spoken of as **gangrenous inflammation**. Thus there is no sharp line to be drawn anywhere between simple adhesive and gangrenous inflammation. One form merges into another, and the effect produced is proportional to the degree of irritation and to the power of the tissues to resist the injurious action of the irritant.

Inflammations are also frequently divided, according to their real or supposed causes, into **Traumatic**, when arising from injury, **Strumous**, **Rheumatic**, **Gouty**, **Syphilitic**, &c. Finally, when the cause cannot be discovered, they are often called **Idiopathic**.

Perhaps, however, the most important distinction is into **Simple localised inflammations** and **Spreading inflammations**. The simple localised inflammations are due to causes which act usually only on a limited area and in a temporary manner. A spreading inflammation is one in which the cause is of such a nature as to be continuously developed either in contact with or in

the substance of the affected tissues, and which, consequently, extends more or less widely beyond the area first affected.

The simple traumatic inflammation resulting from the action of a sharp knife on the tissues is the best example of simple localised inflammation. The effect is accurately limited to the area injured, and unless some new cause be introduced the process cannot extend. Should the discharges become purid, the inflammation will extend as far as the chemical products soak into the surrounding tissues, but no further (p. 182). There is no infection, and the process is still local, though extending more widely from the point of original injury; but should the wound become infected by a pathogenic organism, a true spreading or infective inflammation is developed, the limits of which it is impossible to predict (p. 183).

Inflammation is also divided into **acute** and **chronic**, according to its intensity and duration. The symptoms, terminations and effects that have already been described are those which characterise the more acute and ordinary forms of the process. Chronic inflammation will be described in a subsequent part of this chapter. So-called *catarrhal* inflammation will also be described separately.

Phlegmonous is a term applied to an acute inflammation in which the cardinal symptoms—redness, swelling, heat and pain—are well marked.

Inflammations of organs are also divided into **interstitial** and **parenchymatous**. By the former term is meant that the process is either limited to or most marked in the interstitial fibrous tissue of the organ; by the latter that the special structures, as the epithelium of glands, are implicated in the morbid process.

Croupous inflammation is a term applied to the process when it is accompanied by a firmly coagulated fibrinous exudation, either on the surface of a membrane or in the spaces of its tissue.

The LOCAL SIGNS OF INFLAMMATION may be referred to five heads: viz. 1. *Alteration in Colour*; 2. *Alteration in Size*; 3. *Modification of Sensation*; 4. *Increase of Temperature*; and 5. *Modification of Function of the Part Affected*. The first four of these, redness, swelling, heat and pain (*Rubor et Tumor cum Calore et Dolor*: Celsus), have been described from time immemorial as the cardinal symptoms of inflammation. Certain of these conditions may occur separately, or two or more may be associated together without the existence of inflammation, but it is the peculiar grouping together of them all that most distinctly characterises this pathological condition. The relative intensity of these changes varies greatly, according to the tissue which is the seat of the inflammation; thus, in mucous membranes and in the skin, the alteration in colour is most marked; in areolar tissue, the change in size always attracts special attention; and when a fibrous tissue is inflamed, its sensibility becomes greatly increased. It must not be forgotten, however, that one or another of these signs may be absent, especially pain and heat.

1. **Alteration of Colour** is one of the earliest and most striking signs of inflammation; parts that are naturally perfectly pale, as the conjunctiva, assuming the most vivid red colour when inflamed. The redness is due to the dilatation of the vessels and the accumulation of red corpuscles, and in very acute inflammations, partly to the escape of the red corpuscles from the vessels. The redness of acute inflammation varies with the intensity of the process. Where there is merely determination of blood it disappears completely and readily on pressure with the finger, returning again with the

greatest possible rapidity the moment the finger is removed. When the circulation is retarded, the redness disappears and returns more slowly, and a few red spots may remain unaltered by pressure. These are either points at which the process has reached the stage of stasis, or at which red corpuscles have escaped from the distended capillaries into the surrounding tissue. The tint of the redness varies also according to the activity of the circulation through the inflamed area. When the flow through the vessel is free and rapid, the inflamed surface assumes a bright scarlet tint; but where there is a tendency to stagnation, either from the feeble state of the patient's circulation, or from the inflammation having approached the stage of stasis, the colour becomes a dull purple. The change from bright red to dusky purple is well seen in phlegmonous erysipelas, when the circulation through the inflamed skin becomes impeded, and gangrene is threatening. After acute inflammation it is frequently weeks or even months before the vessels regain their normal tone, and until this has taken place, a certain degree of redness will remain.

Redness is not, however, a constant appearance in inflammation. In non-vascular parts it occurs in the nearest vascular tissues, and not in the part actually suffering from inflammation. In inflammation of the iris the dilated vessels are concealed by the pigment, and the change of tint is from the natural brownish or bluish colour to a greyish or greenish, in consequence of a yellow tinge given to the aqueous humour by the serous exudation into it.

The redness of inflammation disappears more or less completely after death. Where there has been escape of the coloured corpuscles red spots remain, giving rise to the appearance known as "punctiform redness." In septicæmia, pyæmia, and malignant forms of the acute specific diseases, the red corpuscles break up in the blood before death, staining the serum and the lining membrane of the heart and great vessels. A similar staining always takes place after decomposition has set in. It is perfectly uniform, without spots or branching lines, and must be carefully distinguished from the redness of inflammation. Increased redness develops also in the most dependent parts after death from gravitation of blood before coagulation. Thus a coil of intestine hanging down in the cavity of the pelvis may become redder than the rest of the gut, and may be wrongly thought to be inflamed.

2. Alteration in size.—The swelling of inflamed tissues is due to the increased afflux of blood and to the exudation from the vessels.

The swelling varies greatly in different localities. It is greatest in loose textures, and least in those which are firm and dense. Thus, for instance, in inflammation of the areolar tissue of the scrotum, the swelling is much greater than in inflammation of the testis. Inflammation of the conjunctiva occasions great swelling, that of the sclerotic but little. In dense hard structures, such as bone and ligament, there is, of course, very little swelling. If inflammation become chronic, the swelling may terminate in permanent hypertrophy or thickening, as will hereafter be described.

So much of the swelling as is due to hyperæmia disappears after death; that resulting from exudation remains unchanged, and is an important post-mortem sign of inflammation.

3. Modification of Sensibility.—There is in inflammation always more which is owing partly to increased sensibility of the nerves, possibly of blood, but chiefly to the pressure and stretching exercised on the terminal branches by the dilated blood-vessels, and by the inflam-

matory exudation. In inflammation due to chemical irritants, such as the products of putrefaction, it is probably in part due to the direct action of the irritant on the nerve endings.

That the pressure of the dilated blood-vessels really is a cause of the pain in inflammation is shown by the relief derived from the elevation of an inflamed part. In inflammation of the testicle this is especially marked, as the veins leading from that gland are valveless, and in the erect position the weight of a column of blood, two feet or more in length, acts upon the vessels and tends to increase the intra-vascular pressure. We frequently find, therefore, that the patient is altogether free from pain while lying flat on his back; but the moment he rises into the erect position the characteristic sickening, aching, and throbbing sensations return.

In inflammation of organs of special sense, instead of actual pain there may be some alteration in the special nervous sensibility of the diseased organ. When the eye is inflamed, subjective flashes of light may be seen; when the ear is diseased, there may be noises of various kinds.

In inflammation of the bladder, there is a constant desire to expel urine; and in inflammation of the rectum, there are frequent attempts at defecation.

Pain is one of the most prominent symptoms of inflammation, and its existence serves a useful purpose by preventing the patient from using or moving the inflamed part. The intensity of the pain depends more upon the structure affected than on the violence of the inflammation, being, as a rule, greater in proportion as the tissue affected is incapable of yielding to the pressure exercised on it by the dilated vessels and the inflammatory exudation. Hence, in general, the severity of the pain is in inverse ratio to the swelling of the part. Thus, the pain of inflamed bone or fibrous tissue is excessive; that of areolar tissue trifling, and in erysipelas of the scalp most pain is experienced in the ears. In some forms of inflammation pain can scarcely be said to be present; thus, in septic peritonitis there may be little or none.

The character of pain varies according to the seat of inflammation. When mucous membranes suffer, it is often of an itching or burning character, as in conjunctivitis; when the serous membranes of the chest or abdomen are attacked, it is lancinating or stabbing; it is aching in osteitis; throbbing when pus is about to form; sickening when the testis is affected. Inflammatory pain is always increased by pressure; when it is produced principally by pressure, the part is said to be *tender*. This tenderness is of great service from a diagnostic point of view; it may be elicited by direct pressure upon the part, as in squeezing an inflamed testis, or by pressing two surfaces together, as in an inflamed joint. In inflammatory pain, especially of osseous and fibrous tissues, there is very commonly nocturnal exacerbation.

It is important to bear in mind that the pain in inflammation is often referred to other parts supplied by the same nerve as that implicated in the inflamed area. These reflected pains are usually referred to the terminal branches of the nerve. Thus, in hip disease, in which the branch of the sciatic to the joint is implicated, the pain is often referred to the inner side of the knee, where the terminal branches of that nerve communicate with the saphenous and saphenous nerves. In deep-seated inflammation of the face the patient often suffers excruciating pain along the branches of the fifth nerve over the whole side of the head and face. These reflected pains are often of the greatest importance in the diagnosis of deep-seated inflammations.

4. **The Temperature** of an external part of the body when inflamed rises above its normal standard, but not above that of the blood in the left ventricle. In inflammation of internal organs, the temperature rises only as the general heat of the body is elevated by the inflammatory fever. John Hunter originally pointed out this fact; he found, in a case of hydrocele, that a thermometer inserted into the tunica vaginalis stood at 92° F. before inflammation had been excited in the sac, and at 98·75° F. after it had been set up. The conclusion to be drawn from these facts is, that the local increase of temperature in inflammation, when it occurs, is due to the flow of a larger quantity of blood through the part and not to a development of heat in the part itself, dependent on increased tissue-change. This view has been confirmed by the most recent observations, carried out with the greatest exactitude by the thermo-electric apparatus. The opposite view has been maintained by J. Simon, O. Weber and others. The facts that a thermo-electric apparatus has been found necessary to measure the variations in heat, and that observers of the greatest eminence have held opposite views, are sufficient to show that, even supposing heat to be developed locally in inflammation, it cannot be in sufficient quantity to have any appreciable effect on the general temperature of the body or on the local processes in the inflamed part. To the patient, however, there appears to be a real rise of temperature: as Travers truly remarks, "the nerves measure the sensation and not the degree of heat." In many cases the sensation of the patient is that of *burning* in the part, although the actual rise in temperature may be but trifling. This is owing to the exalted sensibility of the nerves.

5. **Modification of Function** invariably occurs in inflammation, and furnishes important local symptoms. The *Functional Activity* of an organ is decreased or abolished during acute inflammation. As an acute inflammation is always the result of some injurious influence which lowers the vitality of the affected part, it is evident that this must be the case. The condition is exaggerated in some cases by the pain, the disordered circulation, and the pressure from exudation. An inflamed muscle is impaired in its power of contraction, and an inflamed gland either ceases to secrete or yields a secretion altered in composition by the admixture of products of inflammation. The *natural use* of a part is often interfered with; thus the bladder can contain no urine, the eye can bear no light, nor can a joint be moved, when inflamed. The normal processes of *nutrition* are either modified or arrested; hence softening, degeneration, or even death of the affected tissues, are common accompaniments of inflammation.

CONSTITUTIONAL SYMPTOMS. The severity of the constitutional symptoms will depend on the intensity, the extent, and the nature of the inflammation, on the previous state of the patient's health, and on the vital importance of the part affected. Thus a moderate degree of inflammation in a part of no vital importance, as the skin, and occasioned by an external cause, as an abrasion, gives rise to no appreciable constitutional disturbance; but if the part affected be of great importance, as the larynx or the kidney, the general symptoms are proportionally severe. The nature of the inflammation and of its cause exerts more influence than any other condition in the constitutional effects. Simple traumatic inflammation gives rise to symptoms of slight severity and short duration; while septic and infective inflammations often prove fatal by the disturbance they cause in the system rather than by their local effects.

Inflammatory or Symptomatic Fever.—The constitutional disturbance in inflammation always assumes the form of fever. Inflammatory fever is a consequence of the local affection. It is thus clearly distinguished from the so-called essential fevers, in which the febrile condition either occurs without any local inflammation or precedes the local affection by a distinct interval, as in the acute specific diseases. The one essential symptom of all forms of fever is elevation of the temperature of the body, or pyrexia; without this, fever cannot be said to be present.

In health, a balance is maintained between heat-production (thermo-genesis) and heat-loss (thermo-lysis), and thus the constant normal temperature is maintained (thermo-taxis). Heat-production takes place chiefly in the muscles and large glandular organs; heat-loss takes place chiefly by radiation and evaporation of water from the skin (70 to 80 per cent.), and by evaporation from the lungs, and warming the air respired (15 to 16 per cent.). Both the production and the discharge of heat are under the control of nerve-centres, the exact situation of which is not determined, but they probably lie above the medulla. Heat-regulation must necessarily also be controlled by nerve-centres. All these centres must also be in some way associated with the vaso-motor centres, as variations in the circulation, in the heat-producing and heat-discharging organs, accompany all variations in heat-production and loss. In fever these various mechanisms are deranged in such a way as to cause an elevation of the bodily temperature, but the heat-regulation, though deranged, is not abolished. The normal morning fall and evening rise persist in almost all febrile conditions, but the variations are greater. Another evidence of the derangement of the heat-regulating mechanism is that external changes of temperature, especially cold, produce a much greater variation in the bodily heat than in health.

It is evident that an elevation of the bodily temperature would result from increased heat-production without a compensating increase of heat-discharge, or from diminished discharge, production remaining the same; and many other combinations may be imagined. There have consequently been many theories of fever, which it is impossible to discuss here, but the following facts may be given as generally agreed upon at the present time.

In fever there is an increased production of heat, not merely a diminished loss. The actual amount of heat produced may or may not be greater than might occur in the same individual in health, on full diet and in active exercise, but it is always out of proportion to the conditions under which the patient is placed as to diet and exercise during the febrile state. That increased heat-production takes place is proved by the evidence of excessive tissue change, such as the disappearance of fat, the wasting of the muscles, the increased excretion of urea and carbonic acid, and by calorimetric observations on animals in which the febrile state has been artificially induced. There is also a considerable increase in the loss of water by the lungs, and often from the skin. In some conditions, such as the rigor following operations on the genito-urinary organs, the contraction of the cutaneous vessels may act as one of the causes of the elevation of temperature by diminishing the loss of heat from the skin; but this is merely an accident and not an essential feature of fever.

The increased production of heat takes place throughout the body, being most active in muscles and glandular viscera. It is certainly not developed to any appreciable extent in the inflamed area, for, as before stated, the latest

observations tend to prove that there is no elevation of temperature above that of the blood in the part actually inflamed; and, even supposing these observations to be erroneous, it is evident, from the difficulty in detecting it, that the heat developed in the area of inflammation must be extremely small in amount and quite insufficient to account for the elevation of the temperature of the whole body by several degrees. The fever is not caused by the pain usually accompanying inflammation; for experiments have shown that irritation of sensory nerves tends rather to lower the temperature by causing a certain degree of shock.

It has been clearly proved by experiment that fever can be induced by injecting into the blood-stream noxious materials of various kinds. Substances which, when thus injected, cause fever are said to possess "*pyrogenic properties*." Amongst the substances possessing marked pyrogenic properties is the lymph returning from an inflamed area, charged, as it is, with the products of the destructive changes which are going on in the part. It has already been stated how largely the flow of lymph is increased during acute inflammation, ounces returning from the diseased part where drachms return from the corresponding sound part. It is evident, therefore, that the effect produced on the blood during inflammation may be very considerable, and will vary with the extent of the inflammation and the amount of local destructive tissue-change which is going on. One substance, which must frequently be present in considerable quantities in the lymph returning from an inflamed area, viz. the so-called "*fibrin-ferment*," possesses very powerful pyrogenic properties. This, it will be remembered, is one of the elements concerned in the formation of fibrin. It is supposed to be yielded up by the white corpuscles which become disintegrated during the process of clotting of the blood. It is found in considerable excess in the serum which can be squeezed out of a freshly formed coagulum; and as coagulation of an inflammatory exudation is the same process as coagulation of the blood, it may reasonably be concluded that fibrin-ferment exists in considerable amount in the serous fluid which drains away from a surface or an area in which an inflammatory exudation is coagulating, to form the so-called "*plastic lymph*." Kohler, Edelberg, Birk, and others investigated the effects of the injection of the free ferment into the circulation of animals, and found that in very large doses it causes coagulation of the blood in the right side of the heart, and death. In smaller doses it gives rise to a febrile disturbance closely resembling that produced by the injection of putrid substances. The fever varies in intensity with the quantity of the ferment injected: and, if this be sufficiently small, the animal recovers without serious symptoms after an elevation of temperature of short duration. There seems to be no reason to doubt the accuracy of these observations. Large numbers of white corpuscles are believed to be disintegrated in the process of coagulation, either of pure blood or of an inflammatory exudation. The theory of "*ferment-poisoning*" may thus, in part at least, account for the fever that always accompanies simple inflammations and large wounds, even with aseptic discharges, and that occasionally follows extensive extravasations of blood. Only under very exceptional circumstances in the human subject could the dose of the ferment be sufficient to cause the more severe symptoms that have been experimentally produced in animals; but possibly the explanation of some cases of death from cardiac thrombosis, that is to say, ante-mortem coagulation of the blood in the right side of the

heart and the pulmonary artery, may be found in the presence of an excess of free fibrin-ferment. The fever produced by the entrance into the circulation of the products of healthy inflammation is the only form to which the term "inflammatory" can properly be applied; but practically, in a very large proportion of cases, the pure inflammatory fever is complicated by a disturbance resulting from the admixture of the products of putrefaction or of specific infective processes with those of the simple inflammation. In fact the products of decomposition are amongst the most powerful of all pyrogenic substances, and we have already seen that locally they are amongst the most potent causes of inflammation. The products of putrefaction of animal substances are so varied and uncertain in their chemical composition that it is better not to attempt to specify them. This much, however, may be said to be proved, that, in the case of ordinary putrefaction, the chemical products, and not the microscopic organisms which invariably accompany the process, are the real exciters both of the local inflammation and of the febrile disturbance. The organisms of simple putrefaction, as before stated, can live only on dead matter; and, if they happen to enter the circulation, they speedily perish, unlike the true parasitic or pathogenic organisms which accompany many infective processes and grow and flourish in the living tissues or blood. The effect produced by the absorption of the products of putrefaction is, therefore, proportional to the dose: the poison has no power of multiplying in the system and, if the dose be not too great, it is speedily eliminated without serious consequences. If the dose be excessive, it gives rise to a train of symptoms which will be described in the chapter on septicæmia. The products of putrefaction are absorbed with great readiness from a raw surface or the charred surface left by a burn: but it is said that the ease with which they are taken up is greatly diminished by the application of some chemical caustics, especially chloride of zinc. Healthy granulation-tissue forms an efficient barrier to absorption under ordinary conditions (presumably from its possessing no lymphatics); but at slight degrees of pressure the pyrogenic substance passes readily through it. Thus in a large wound, such as an amputation, if there is perfect drainage and no decomposition, the febrile disturbance is very slight and of brief duration, ceasing by the third day at the latest: if there is decomposition of the discharge the fever is higher, and reaches its maximum by the third day, subsiding gradually as the granulations spring up and form a barrier against further absorption; if with decomposition there is insufficient drainage and the wound be of sufficient size, the patient may receive such a dose of the products of putrefaction as to die poisoned—a condition which will be described in the chapter on Septicæmia. If after the granulations have sprung up and fever has ceased, an accumulation of putrid matter takes place in the bottom of the wound, and there is such a want of drainage that the fluid is kept up at some degree of pressure, the fever and local inflammation will return; but should the drainage be made perfect, they will again cease. It is not clear due to these two causes—the products of destructive tissue-change in simple inflammation, and the pyrogenic products of putrefaction in septic inflammations—that is commonly spoken of as "surgical or traumatic fever;" but these terms should properly be limited to the former, and these conditions as being a fever inseparable from any large wound or abscess even when subcutaneous, and the term "septic fever" should be reserved for the latter.

Fever is also a constant accompaniment of acute infective inflammations: that is to say, of those conditions in which a virus is present, which has been proved in most cases to be a micro-organism, which multiplies in the living body, either locally, as in local spreading or infective inflammation, or generally, after entering the blood from the original centre of infection, as in many forms of septicæmia and in pyæmia, malignant pustule, &c. The fever in these cases is due, in part at least, to the admixture of the chemical products of the growth of the organism with the blood. That these substances are capable of exciting fever has been proved by the injection of the products of their growth on artificial cultivating media.

Fever may also be caused by the presence in the blood of chemical substances generated in the body itself. The most simple example of this is the fever that accompanies an attack of gout.

It has before been pointed out that heat-production, heat-discharge, and heat-regulation are under the control of the central nervous system. Two theories have been held with regard to those fevers which are due to the admixture of pyrogenic substances with the blood: the first is that the pyrogenic substance acts directly on all the tissues of the body, giving rise to increased tissue-change with development of heat; and the second is that the impure blood circulating through the brain disturbs the heat-controlling centre, and thus indirectly acts on the tissues. The latter is the view generally accepted at the present time.

We are yet very far from fully understanding the exact nature of fever: but what we do know is of immense practical value. We know that in the majority of cases in which fever forms a serious feature in surgical practice, it is due to the entrance into the circulation of noxious materials generated locally, and that in its treatment our first object must be to arrest the formation of the pyrogenic material by local means. For example, in an acute abscess a fluid containing the products of destructive tissue-changes is pent up in a cavity at some degree of pressure, and a certain proportion of the pyrogenic material it contains is constantly finding its way into the circulation. Open the abscess and cut off the supply and the fever at once subsides; but if, for want of drainage, the cavity fills again and its contents be allowed to decompose, the fever will return more severely than before, as putrid matter is more powerfully pyrogenic than the products of simple inflammation; open up the cavity and drain it, and again the fever will subside; but possibly, supposing the patient to be exposed to infection in an unhealthy and overcrowded hospital, a virus, capable of multiplying in the surrounding tissues, and perhaps of increasing, like a ferment, in the blood itself, may find its way from without into the abscess cavity and thence infect the whole system. Under such circumstances, the mere local treatment will no longer be able to arrest the febrile disturbance; and, unless the patient have sufficient vitality to resist its effects, a fatal result must follow.

Symptoms of Fever in General.—Although inflammatory fever or pyrexia presents clinically many varieties, certain symptoms are common to all. The first and most important of these is *elevation of temperature*, as shown by the thermometer. All temperatures above 99.5° F. (37.5° C.) must be considered as indicating fever. The fever is considered slight unless the thermometer rises above 100.5° F. (38° C.); up to about 102.5° F. (39° C.) it is considered moderate; from 102.5° F. (39° C.) to 105° F. (40.5° C.) it is

spoken of as high fever, and above that point the term *hyperpyrexia* is applied to it. Few patients recover from any febrile condition in which the thermometer rises above 107° F. (41.6° C.).

The temperature is usually taken in the axilla, but occasionally the mouth or rectum is used instead. In taking the temperature in the mouth, the bulb of the thermometer must be put under the tongue and the lips kept firmly closed for three minutes. In the mouth and rectum the temperatures registered are about half a degree higher than those in the axilla. The temperature in all inflammatory fevers shows the morning fall and evening rise, common to nearly all febrile conditions.

Many febrile conditions arising in surgical practice, especially those connected with acute suppuration and some forms of blood-poisoning, are ushered in by *chilliness*, *shivering*, or a *rigor*. A well-marked **rigor** commences with a sensation of cold, accompanied by great nervous depression and anxiety, often amounting to fear, on the part of the patient. The feeling of cold is so intense that the patient covers himself with hot clothing and shivers beneath a heap of blankets till his teeth chatter. If during this *cold stage* of the rigor the temperature be taken in the mouth, it will be found to be greatly above normal, often as high as 105° F. If the temperature had been taken before the rigor commenced it would have been found that the rise in the thermometer began some time before the sensation of chilliness set in. During the cold stage the face is pale and the whole surface of the body is more or less blanched. The surface temperature of the extremities is not raised and may be subnormal. This is due to the contraction of the arteries of the skin, which is the essential feature of the cold stage of a rigor. The bloodless condition of the skin thus induced is the cause of the sensation of cold, and by limiting the loss of heat from the surface it takes some part in producing the rapid elevation of temperature. After a time varying from ten to twenty minutes or even more, the contraction of the cutaneous arteries yields, and a corresponding dilatation follows. The surface of the body becomes red, the face is flushed, the skin becomes moist, and gradually a profuse perspiration sets in—sufficient, in many cases, to soak the sheets of the bed. During this *hot stage* of the rigor, the patient feels intensely hot, although the thermometer shows that the temperature is rapidly falling, the loss of heat from evaporation of the perspiration being necessarily very great. In half an hour or more the sweating ceases and the whole rigor is over, leaving the patient weak and exhausted.

In all forms of fever there is *increased frequency of the heart's beat*. This is, as a rule, proportional to the elevation of the temperature and to the degree of weakness of the patient. The respiration is increased in frequency, usually in the same proportion as the pulse. The face is generally flushed, but by no means always so.

Another feature common to all forms of fever is *emaciation and loss of strength*. The increased production of heat must be regarded as work, and consequently during febrile disturbances the patient may be expending force as much as if he were carrying weights or climbing mountains. At the same time, his appetite is lessened and his powers of digestion and assimilation of food reduced. The rapid exhaustion and emaciation of many fevers is therefore not to be wondered at.

Thirst is always one of the most prominent symptoms, and the *appetite* is

diminished or lost. In almost all high febrile conditions there is *dryness of the skin*; for, although in fever there is an increased elimination of water, this takes place chiefly by the lungs. The mucous membrane of the alimentary canal also secretes less than natural, and to this cause are due the *dry tongue*, the accumulations on the teeth and lips or *sordes*, and the *constipation* so commonly met with in fever.

In all febrile conditions there is a feeling of lassitude or weariness, and a marked disinclination to bodily or mental exertion. Headache is a common symptom. In the earlier stages of very acute febrile disturbance, there may be *delirium* of a violent form; in the later stages, when the strength is becoming exhausted, wandering or muttering delirium is common. The patient's sleep is disturbed, he is restless at night, and delirium is more often met with at that time than during the day.

Fever is said to *terminate* by **Lysis**, when the symptoms gradually subside; and by **Crisis**, when the fall of temperature is sudden. In the latter case, it is often accompanied by a "*critical evacuation*," as a free flow of urine containing a large quantity of lithates, a profuse perspiration, or a watery discharge from the bowels.

Severe fever of any kind always leaves the patient weak and anæmic, in consequence of an excessive destruction of the red corpuscles. In the most extreme forms of septic fever, this takes place to such an extent that the plasma becomes stained during life by the colouring matter of the disintegrating corpuscles.

The **urine** in all febrile conditions is scanty and high-coloured. It contains an excess of urea and urates, and often a deficiency of chlorides. Albumen is frequently met with in all forms of fever.

The **blood** in inflammatory fever doubtless undergoes important changes, but their exact nature is still imperfectly understood. In the days when venesection was a regular part of the treatment of every febrile condition, much attention was paid to the blood that was drawn. It was noticed that in many acute inflammatory affections the blood coagulates slowly, and—partly from this cause and partly from the rapid running together of the corpuscles into dense masses, which sink quickly—an upper colourless layer of coagulated fibrin free from red corpuscles is left at the top of the clot when it is allowed to form quietly in a deep vessel. The tough layer of yellowish fibrin thus formed received the name of the "*buffy coat*." The absence of corpuscles allows the contraction in the colourless part of the clot to be much more complete than elsewhere, and its upper surface consequently is depressed in the centre, being "*cupped*," as it is termed. The "*buff and cup*" were formerly much used as guides in estimating the intensity of the inflammation; it has, however, been shown that the buff may occur in other conditions of the system, as in plethora, or pregnancy, or after exercise, without the occurrence of inflammation. The cupped shape of the clot is in some degree dependent on the shape of the vessel into which the blood is received, being most marked when it is deep.

The changes that occur in the plasma are due chiefly to the admixture therewith of the products of inflammation taken up from the affected part by the lymphatics and blood-vessels; and it is evident therefore that they must vary considerably according to the nature and intensity of the local process. If the inflammation affects some important organ, the function of which is to

take part in the preparation of the blood, or to eliminate from it the products of tissue-change, its composition must be materially altered; but it is at present impossible to state with any definiteness the exact nature of the changes that take place. In simple inflammations, the fluid draining away from the inflamed area contains, as before stated, an excess of the so-called fibrin-ferment, and it is possibly due to this that the amount of coagulated fibrin which can be obtained from a given quantity of blood is increased in some inflammatory affections. In inflammations accompanied by putrefaction of the discharges, the products of decomposition are added to the fluids entering the circulation by means of the lymph-stream, and with these, microscopic organisms often find their way into the blood. The bacteria which accompany ordinary putrefaction soon perish in healthy blood, being apparently incapable of finding nutriment amongst living tissues. In true infective inflammations, the inflammatory products which enter the blood-stream may in some cases bear with them organisms capable of multiplying amongst the living tissue and giving rise to secondary local mischief or fatal general disease.

The *corpuscles* of the blood, both white and red, may show considerable deviation from the normal standard in number during inflammation. There is no reason to believe that in simple inflammations there is any material change in the number of red corpuscles; but in infective inflammations with high fever and in those accompanied by the absorption of the products of putrefaction, there is undoubtedly a rapid destruction of the red corpuscles. In these cases they often show a tendency to aggregation in irregular clusters instead of the well-formed rouleaux seen in normal blood. The number of white corpuscles in the blood during inflammation has been said by Virchow, Gulliver, and others, to be increased. T. P. Gostling has made a series of observations on this point in the wards of University College Hospital. The corpuscles were counted by means of Gowers's hemocytometer. The conclusions arrived at were briefly as follow: The white corpuscles are increased in the blood in all inflammations reaching the stage of suppuration, especially if the pus is pent up in a cavity; they are also slightly increased in parenchymatous inflammations such as acute pneumonia. They are not increased in inflammations accompanied only by "serous or sero-fibrinous exudations." According to Virchow, the increase in the white corpuscles is due to stimulation of the lymphatic glands, through which the excessive lymph-stream passes from the area of inflammation.

Varieties of Acute Surgical Fever.—Acute inflammatory fever presents infinite variety of form: the type which it assumes being dependent, first on the nature of the pyrogenic substance the admixture of which with the blood is the cause of the disturbance; secondly, on the previous health and strength of the patient; and thirdly, on the occurrence of certain local symptoms determined by the seat of the inflammation. These varieties in the type of the fever arrange themselves practically into two classes—1, *sthenic*, and 2, *asthenic*. The terms "*sthenic*" and "*asthenic*" are not used at the present day with reference to varieties of inflammation as they were in former times; but for the designation of the different forms of febrile disturbance, as viewed clinically, we have no better names, and it is convenient to continue to employ them.

1. *Sthenic Inflammatory Fever* occurs in young or middle-aged individuals

of healthy constitution. It is the form usually assumed by the fever that results from the absorption of a moderate quantity of the chemical products of putrefaction from a large wound during the first week after its infliction, and it is also often seen in acute inflammations of important organs, or during the formation of acute abscesses.

The stage of invasion is slightly marked: there is chilliness or shivering with a feeling of general illness; but these symptoms may be so transient as to escape observation. In the majority of cases it is not until the constitutional disturbance is fully developed that it attracts attention. The skin is hot, and there is a rise in the temperature of the body of from 2° to 5° Fahr. The evening temperature is one or two degrees higher than that observed in the morning. There is a feeling of general languor, and the head is often heavy and hot. The pulse is full, bounding or thrilling, and quickened to thirty or forty beats in the minute above its normal rate. The character of the pulse varies with the part affected and with the cause of the fever. In ordinary traumatic fever, when it assumes the sthenic form, in the formation of acute abscesses, and in the early stages of many specific inflammatory fevers, as erysipelas, the pulse is full and bounding; in inflammation of glandular structures, as the testis or mamma, it is compressible though full; in acute inflammation of serous membranes, as in pleurisy, peritonitis, or meningitis, it is small, compressible and wiry. The secretions are arrested or diminished in quantity, the tongue is coated with a white fur, and the mouth clammy, usually with much thirst: the bowels are confined, and the skin dry. The urine is scanty and high-coloured.

In surgical cases the fever commonly terminates gradually, by *lysis*, but it may cease suddenly by *crisis* if the local cause can be removed. The tongue becomes clean, the pulse lessens in frequency and in strength, the secretions become more free, the thirst diminishes, and strength and appetite return. This favourable termination can occur in most surgical cases only by the removal of the cause of the fever, as by the opening of an acute abscess, the removal of septic matter by drainage, or the growth of healthy granulations preventing its further absorption. Should the cause persist, the fever may terminate in death, either by exhaustion or by the superintention of some visceral complication, as pneumonia; or the sthenic form may gradually merge into the type that is characterised by debility.

2. *Asthenic Inflammatory Fever* occurs in those individuals whose constitutions are broken down by privation, dissipation, or by any of the general depressing causes of disease, as grief, anxiety, long residence in a vitiated atmosphere, or old age. In constitutions such as these, frequently met with in all classes, but especially amongst the poorer residents in large towns, inflammatory fever almost invariably assumes this type. The cause of the fever, however, in many cases, determines the type quite as much as the constitutional state of the patient. When it is due to a large dose of the products of putrefaction rapidly absorbed it is asthenic from the first, or rapidly becomes so. The same form is met with in almost all true cases of infective blood-poisoning from wounds: that is to say, in those cases in which the poison which enters the system is not merely the chemical products of putrefaction, but a ferment-like substance capable of multiplying in the living body, as in acute septic infection, pyæmia and malignant pustule. In all spreading gangrenous inflammations the fever assumes the same form; and in ery-

tipulas, although, as before stated, there may be asthenic fever for a short time, the signs of exhaustion rapidly set in. As the asthenic form of fever depends so frequently on general infective processes it is often accompanied by secondary complications, as pleurisy, pneumonia, visceral abscesses and the like.

When the asthenic form comes on as a sequel of the sthenic, the symptoms of the one gradually merge into those of the other, the weakness increases, the pulse becomes feebler though its frequency is kept up, the tongue becomes brown and dry, and there is tendency to delirium of a muttering kind.

When the fever assumes the asthenic form from the very first, depression is often strongly marked during the period of invasion: and, even when the febrile state is fully established, the symptoms are not very active. There is throughout an appearance of heaviness and stupor about the patient, and an early tendency to delirium of a low and muttering form, especially at night; the pulse is feeble and very frequent: the skin may be hot and dry, or sometimes moist and clammy; the temperature is from 2° to 5° Fahr. above normal, and shows a marked evening rise and morning fall; the tongue is brown and dry, and scales rapidly accumulate about the lips and teeth; the cheeks are often flushed, and the eyes may be bright and staring. If the patient recover, there may be a critical evacuation, as sweating or diarrhoea; the pulse subsides in frequency and increases in strength, the tongue gradually and slowly cleans from the sides and tip, the temperature falls often below normal for some days, and the patient slowly and imperfectly regains his strength. Owing to the extreme feebleness of the heart's action that often accompanies this form of fever there is a great tendency to local congestions, especially hypostatic pneumonia, which may interrupt progress towards recovery.

If the disease take an unfavourable course, the weakness of the pulse and the dark incrustation of the tongue increase; the temperature often falls below normal; the skin becomes cold and clammy; hiccough, subsultus and dyspnoea supervene; the muttering delirium gives way to insensibility or even to coma, and death occurs from exhaustion, or as the result of visceral complication. It is this condition that is frequently described as the "setting in of typhoid symptoms."

In patients whose nervous systems have been shattered by intemperance, or who have been exhausted by excessive mental work or excitement, the nervous symptoms that accompany the febrile disturbance may form so prominent a feature of the case as almost to justify the description of a third type, as has been sometimes done, under the name of **Irritative Fever**. In these cases, if the fever assume the sthenic form there is high delirium, often of a furious kind, with wildness of the eye, flushed face and heat of head. More often the fever is from the first of the asthenic type, especially in habitual drunkards, in whom it resembles delirium tremens: there is the same tremor, clammy perspiration and foul tongue, and the delirium is not violent but busy and muttering, the patient being restless and constantly trying to get out of bed; or is sleepless, and unless relief be obtained, signs of debility rapidly show themselves, and death takes place either from exhaustion or coma.

TREATMENT OF ACUTE INFLAMMATION.

The knowledge we obtain of the causes and nature of inflammation in the dead-house and in the pathological laboratory serves to some extent to guide us

in its treatment. Still our knowledge is not yet sufficiently perfect for theory alone to direct our practice, and we must on no account neglect those modes of treatment which have been shown by experience to be of use.

Before describing in detail the means adopted in surgical practice for the prevention and cure of inflammation, it will be well briefly to point out the indications furnished us by pathology.

1. Inflammation is the result of an injury done to the living tissues, of sufficient severity to lower the vitality of the affected part, but not actually to kill it. Our first object, therefore, in the prevention of inflammation, is *to protect the tissues from all sources of irritation and, failing this, to remove the original irritant as quickly as possible, and to prevent the introduction of fresh causes of irritation.*

Under this head are included :—the removal of foreign bodies ; the avoidance of irritating applications ; the prevention of tension, by drainage of wounds and suitable position of injured parts ; the relief of tension, as by early opening of abscesses, or by incisions to allow of the escape of inflammatory exudation ; and the prevention of decomposition in the discharges of wounds and abscesses, and the exclusion of specific infective poisons, such as that of erysipelas, or the like.

2 All irritants lower the vitality of the tissues upon which they act, and if of sufficient intensity, cause death of the part. The degree of damage done is proportional, first, to the intensity of the irritation, and, secondly, to the vitality, or, in other words, to the power of resistance of the tissues. In the prevention of inflammation, or in the limitation of the process, our first object must be to do everything in our power, both by general and local means, *to promote the healthy nutrition of the tissues.*

Under this head come :—attention to diet ; avoidance of alcoholic excess ; regulation of the action of the bowels, skin and kidneys ; the treatment of constitutional conditions, such as gonorrhoea, rheumatism, and syphilis. Locally the chief objects to be kept in view are—to preserve a normal state of the circulation by removing causes of congestion, or local anæmia, as by the excision of tumours pressing on vessels, the cure of varicose veins, and the relief of the distended capillaries by uniform elastic pressure : by elevation of the part, or the removal of strangulation ; to maintain a normal temperature ; and to avoid over-work of the part, as excessive use of the eye or larynx.

When the inflammatory process is established, the vitality of the part is lowered, and our main objects are—to avoid further depression, which might extinguish such life as remains ; to encourage the return of vitality by the maintenance of a normal temperature and by the regulation of the disturbed circulation by such means as we have at our command ; and to ensure as far as possible both functional and mechanical rest of the inflamed part.

Inflamed parts are less able to withstand the effects of heat and cold, of chemical irritants, or mechanical violence. Thus, the application of cold or of powerful antiseptic solutions (all of which are more or less irritating), or the necessary injury of a surgical operation, may, in an inflamed part, intensify the process, and even cause sloughing.

3. The essential phenomena of inflammation are : first, the dilatation of the arteries with increased blood-pressure in the area supplied by the dilated vessels ; secondly, the exudation through their damaged walls, which, other things being equal, will be proportional to the degree of intravascular

pressure; thirdly, the migration of the white corpuscles; fourthly, the complete arrest of the circulation by stasis. The vascular dilatation and exudation cause the inflammatory swelling and give rise to tension, which, acting as a fresh source of irritation, aggravates the inflammatory process. One of the primary objects in the treatment of inflammation is *therefore to limit the exudation by diminishing the blood-pressure and, failing in that, to relieve the tension it gives rise to.* The blood-pressure may be limited, first, by general means acting upon the heart, as aconite, antimony, and general blood-letting; and, secondly, by diminishing the quantity of fluid circulating in the body, as by general blood-letting, saline purgatives, or low diet. The local blood-pressure may be diminished by causing dilatation of the vessels of some other parts—as of the intestines by purgatives in external inflammations, or of the skin by diaphoretics in internal affections; secondly, by causing contraction of the vessels supplying the inflamed area by the direct application of cold, belladonna, or astringents, or by employing a stimulus at a distance, so as to cause a reflex contraction of the vessels of the diseased part, as in counter-irritation by blisters or mustard plasters; thirdly, by causing a uniform dilatation of all the vessels of the inflamed part and its immediate neighbourhood, so as to lessen local resistance, as in the application of heat; and, fourthly, by elevation of the affected part of the body, by which the return of blood from the part is favoured, and, as has been shown by Lister, a certain degree of arterial contraction induced. Direct pressure on the main artery of the limb would also come under this heading. When exudation is taking place, elevation of the limb favours its return by the lymphatics, and so lessens swelling. Should the part become so much distended as to threaten gangrene from pressure on the vessels, the exudation may be allowed to escape directly by incisions, punctures or scarifications. The migration of the corpuscles is limited by cold, which arrests their amoeboid movements, and by all means which diminish blood-pressure. Heat favours their migration, and also encourages their moving out of the inflamed area into the lymphatics, in cases in which resolution is taking place. It is only the return of vitality in the walls of the vessels, however, that can completely arrest the process of migration.

The tendency to inflammatory congestion, that is to say, choking of the distended vessels with scarcely moving blood, can be relieved in some cases by drawing blood directly from the part by scarification or puncture, or the force of the heart's action may be stimulated by the administration of alcohol in order to drive the blood past the obstruction. Stasis can be relieved only by the general means above mentioned for favouring the return of vitality in the inflamed area.

4. Pain, which forms so prominent a symptom in many inflammations, will be relieved locally by those means, already mentioned, which tend to diminish tension: but in addition, local sedatives—as belladonna, opium, or subacetate of lead—are often of great use. If these fail, sedatives must be given internally.

5. Lastly, the treatment of inflammation includes that of the *febrile disturbance* which accompanies it. This, as we have seen, may be due chiefly if not entirely to the admixture with the blood of the exudation returning from the inflamed part by the lymphatics; in such cases the means adopted to limit the exudation, or to drain it away externally, as in a wound, will limit the fever: in other cases the stream of lymph bears with it the chemical pro-

ducts of decomposing matter from the inflamed area, and thus acquires an additional power of causing fever; this can be prevented only by proper antiseptic precautions, or by draining off the exudation externally. In specific infective inflammations the fever may be due to contamination of the blood by the presence of some poison multiplying in it, as in septicæmia (septic infection), pyæmia, or malignant pustule. At present we are not acquainted with any means of definitively destroying the poison in such cases; we can only support the patient in every way in our power, by food and careful nursing, so as to enable him to withstand its evil influence. In those cases in which the nervous symptoms of fever are predominant, sedatives must be administered internally. Lastly, certain drugs are used empirically, from their known power of reducing the temperature in fever, amongst the most important of these being alcohol, quinine, salicylate of soda, aconite, antipyrin, antifebrin, phenacetin, &c. The application of cold generally to the body by baths or wet packing, or locally to the head by an ice-cap, as recommended by Knowsley Thornton, useful as they undoubtedly are in cases of very high fever, are but empirical modes of treatment, as they attack one symptom only, leaving the cause untouched. *No Surgeon should rely solely on such means as these unless it is beyond his power to discover, or to remove, the cause of the fever by cutting off the supply of the pyrogenic substance, as by opening an abscess, establishing proper drainage in a wound, or cleaning out septic matter from any cavity in the body.*

The above principles serving more or less as our guides, we can now consider more in detail their practical application in the treatment of acute inflammation.

THE PREVENTIVE TREATMENT of inflammation can be employed only in cases of injury. All injuries of any severity—as cuts, bruises, sprains, or fractures—must necessarily be followed by a certain degree of inflammation; but this simple traumatic inflammation has no tendency to spread beyond the area injured, which, in the case of a clean-cut wound, is little more than a microscopic layer of tissue; nor does it tend to pass beyond the stage of simple exudation into that of suppuration or ulceration, unless some further cause of irritation come into play after the injury. When we talk, therefore, of the prevention of inflammation, we do not mean the prevention of the simple adhesive inflammation which follows an injury, for that is impossible; but we mean the exclusion of all sources of irritation which could intensify or prolong the process or make it assume a spreading form. The irritants we have chiefly to guard against are the products of putrefaction and the specific poisons of the various infective inflammations. The essential cause of putrefaction being an organised ferment, and the actual virus of almost all infective inflammations being of the same nature, the exclusion of micro-organisms from the injured area forms the most essential part of the preventive treatment of inflammation. The simple non-pathogenic, or septic organisms, cannot live in the blood-stream, and consequently always find their way to the injured part directly from without, being carried to it either by the air, or in water, or on solid bodies, such as the instrument inflicting the wound, or the Surgeon's hands, or from the patient's own skin. On the other hand, there is strong reason to believe that some pathogenic organisms may enter by the lungs or alimentary canal and be carried by the blood-stream to the injured part, although, doubtless, they far more commonly enter an open

wound directly from without in the same way as the non-pathogenic organisms. Local means calculated to exclude or destroy micro-organisms will prevent putrefaction almost with certainty. The same means will also prevent the great majority of infective inflammations. The association of putrefaction with the specific infective inflammations is so close that the two subjects cannot be dealt with separately in so far as local treatment is concerned, and here, therefore, we need deal only with the prevention of putrefaction.

The **prevention of putrefaction** may be carried out by the exclusion of any one of the essential conditions for the process (p. 177). The first of these is the presence of dead organic matter. It is our object, therefore, by drainage of wounds and abscesses, either entirely to remove the putrescible matter or to reduce it to so small a quantity that the effects of its putrefaction will be insignificant. The next three conditions, the presence of oxygen, water, and a certain degree of temperature, cannot be excluded from any abscess, wound, or cavity of the body; but the discharges flowing from these may be either received in some absorbent material or allowed to dry in the air, and thus their decomposition may be prevented; and it will be seen, in the treatment of wounds, that these methods are often adopted. The last condition of putrefaction is the presence of the organised ferment; and the destruction or exclusion of this forms the essential feature of those modes of treating wounds, abscesses, or ulcers, which aim at the prevention of the inflammation which results from the irritation of the chemical products of putrefaction. The simplest mode of exclusion of the organisms floating in the air is by *filtration*. It has been shown by experiment that the air filtered through pure cotton-wool is incapable of giving rise to putrefaction or other fermentative changes; but this mode of preventing decomposition and infection, although often forming an accessory to other means, can scarcely ever be employed alone in surgery. Septic organisms are much more commonly carried by water or by solid bodies, as the Surgeon's hands or instruments, and consequently our chief reliance has to be placed on *chemical antiseptics*—that is to say, on chemical substances capable of destroying the vitality of minute vegetable fungi. It must not be forgotten, however, that all chemical antiseptics are in themselves irritants; and in using them care must be taken to protect the tissues as far as possible from their direct action, otherwise they may act as causes of inflammation although preventing putrefaction. As we shall have frequently to refer to the use of antiseptics in the treatment of abscesses, ulcers, and wounds, it will be most convenient here to mention the chief substances at present employed, with their properties and peculiarities. Antiseptics vary much in their power, in the irritation they give rise to, and in their effects if absorbed; these points will therefore be alluded to.

It may be stated that no antiseptic vapour, of which any practical use can be made in surgery, has yet been discovered.

Carbolic Acid is, perhaps, still the most extensively used of all antiseptics, though by no means the most powerful. In surgery the purest acid any should be used, the form known as absolute phenol being the best. The impure acid, such as is used for disinfecting drains, is more difficult of solution in water, and its smell is very offensive. The pure crystallised acid may be made permanently to assume the form of a dense oily liquid by the addition of about $\frac{1}{10}$ th of its bulk of water, but true solution does not take place till the proportion of water is about 19 to 1 of the acid, thus forming the 1 in 20

solution. The efficient strength of the watery solution as an antiseptic is about 1 in 50, below which it must not be reduced. Carbolic acid is readily soluble in oil or glycerine in any proportion up to equal parts. The preparations used in surgery are :—*Watery solutions*, 1 in 20 and 1 in 40. The former is applied to foul wounds for the purpose of cleaning them, to wounds which have been exposed to the air for some time, and to the unbroken skin round the region in which an operation is to be performed; the latter is used to wash the operator's hands and the sponges, and all instruments used during the operation, and to irrigate the wound during the performance or to wash it out at the end before closing it. The 1 in 20 solution is used for the spray, as will hereafter be described. Both the 1 in 20 and the 1 in 40 solution whiten any raw surface to which they may be applied, but their action is very superficial, and does not interfere with primary union of a wound. At the moment of application they cause severe smarting, but this is soon followed by a sensation of numbness. *Oil solutions* act much less powerfully than the watery. For preserving catgut ligatures a solution of 1 in 5 must be used. In the strength of 1 in 10 it may be applied on lint to a wound as an antiseptic dressing, but it loses its acid rather quickly, especially if there is much discharge, and consequently must be renewed at least twice or three times a day. *Glycerine solutions*. The pharmacopœial solution of 1 in 5—one part of carbolic acid to four of glycerine—is too strong for application to a raw surface, but may be used on the unbroken skin; for wounds the solution may be reduced to 1 in 10 by the addition of an equal quantity of water or glycerine. If used as an antiseptic dressing it must be changed frequently, as it is readily washed out of lint by the discharge. *Carbolic gauze*. This is a coarse gauze impregnated with carbolic acid dissolved in a mixture of paraffin and resin. It contains about $\frac{1}{2}$ th part of carbolic acid. It forms an absorbent dressing, and possesses the great advantage of yielding up its carbolic acid slowly, and thus retaining its antiseptic properties for a long time. *Carbolised cotton-wool and tow* have also been used, but are somewhat inefficient preparations.

Carbolic acid may act injuriously both locally and generally. If the solution be not properly prepared, small globules of the undissolved acid may be floating in it which will cauterise both the patient's tissues and the Surgeon's hands. To avoid this it is better always carefully to measure the acid and to prepare the solutions some hours before they are used. If the solution is prepared immediately before use it must be well stirred; and, if it is not required to be cold, warm water may be used to ensure perfect solution.

Carbolic acid is, even in the strength of 1 to 40, an irritant to the living tissues; when applied to a wound it exaggerates the serous discharge for the first twenty-four hours, and consequently increases the necessity for good drainage. In using it as a dressing the object of the Surgeon must be to prevent direct contact of the acid with the raw surface as far as possible after the wound has been once washed out; otherwise it may give rise to suppuration. In washing out a wound also it is important to take care that the lotion used escapes freely. If it remains in hollows and cavities of the wound its absorption may cause poisoning; and if it be forced into the spaces of the areolar tissue, considerable local inflammation may supervene. In some patients the skin is singularly intolerant of the acid, and the gauze may cause even vesication. Its use must then be abandoned, and some other anti-septic employed in its place.

Carbolic acid cannot be applied either to the unbroken skin or to a raw surface without a certain quantity being absorbed. As a rule this gives rise to no unpleasant symptoms; but, if the surface be very large or the patient be peculiarly intolerant of the acid, symptoms of carbolic poisoning may arise. In every case in which a carbolic acid dressing of any kind is applied, it or its derivatives can be detected in the urine by proper tests; and if a surface of any size is covered by the dressing or a large wound is washed out with the lotion, the urine frequently undergoes a marked change. In the mildest cases it is passed clear, but after standing for some time gradually assumes an olive-green tint; in the more severe cases it is passed dark in colour, and on standing becomes almost black. If no other symptoms are present this need give rise to no anxiety. In cases in which the graver symptoms of poisoning are present, the sulphates disappear completely from the urine. The most marked feature of carbolic acid poisoning by absorption from a wound is severe and uncontrollable vomiting; if the dose has been very large, collapse speedily sets in, with insensibility of the pupil, twitching of the muscles, a rapid feeble pulse, and a subnormal temperature. Albumen is said to appear in the urine. In other cases elevation of temperature has been noted, with vomiting followed by insensibility and death. With the exception of a few recorded cases, which must be attributed to an idiosyncrasy on the part of the patient, dangerous symptoms have occurred only when the carbolic lotion has found its way into some cavity as the rectum, peritoneum or pleura, or when large abscess-cavities have been washed out with the lotion, or when it has been forced into the spaces of the areolar tissue in attempts to disinfect deep wounds or compound fractures. The treatment consists in immediately removing all carbolic acid dressings and substituting some other antiseptic. The patient must be supported by stimulants, especially hypodermic injections of ether; and friction of the surface should be employed. Ice may be given to allay the vomiting. Baumann has recommended the administration of sulphate of soda in small doses frequently repeated, with the hope of converting the carbolic acid into the non-poisonous sulpho-carbolate. This treatment was suggested by the disappearance of the sulphates from the urine, which is possibly due to their having been consumed in that way; the graver symptoms supervening when they are exhausted and free carbolic acid becomes present in the blood. Treeding can do no harm and should always be tried.

Carbolic acid has now been more than twenty-five years before the profession as an antiseptic, and has derived great importance from being the agent first selected by Lister for his antiseptic system of treating wounds. In spite of the efforts of Lister himself and other Surgeons to find some substitute which shall be free from the inconveniences attending the use of carbolic acid, it still holds its place as one of the most generally useful and efficient of all antiseptics. It has no injurious effect on steel, and consequently it is used for disinfecting surgical instruments even by those Surgeons who employ some other substance for cleaning their hands and washing out or irrigating wounds.

Salicylic Acid is a derivative of carbolic acid, possessing no toxic properties. It requires at least 300 parts of cold water to dissolve it, and is in this form a less certain antiseptic, though less irritating, than carbolic acid. The preparations used in surgery are *salicylic wool*, *salicylic jute*, and *salicylic oil*. The jute is recommended by Thiersch as being more absorbent; the

silk is prepared from refuse material, and was introduced by McGill of Leeds: it is very absorbent and elastic. All these preparations contain a proportion of the acid varying from 3 to 10 per cent. They should be moistened with a little glycerine to prevent the dust of the acid from flying about when they are used, as it causes violent sneezing. Salicylic acid in solution corrodes instruments.

Perchloride of Mercury.—Attention was first directed to corrosive sublimate as an antiseptic by Koch, who showed that in the extreme dilution of 1 in 20,000 it was capable of killing, in ten minutes, the spores of the *bacillus anthracis*, one of the most resisting of all known organisms. The results of these experiments cannot, however, be applied without modification to the prevention of decomposition in albuminous fluids, for corrosive sublimate forms with albumen a compound known as "mercuric albuminate," which, although not inert, possesses far less active antiseptic properties than the watery solution. Thus, Mikulicz found that the addition of one part of corrosive sublimate to 2,000 parts of a mixture of equal parts of blood and water entirely failed to retard putrefaction and the development of bacteria: when added in the proportion of 1 in 1,000 these processes were retarded, but not prevented, and it was not till the proportion of 1 in 400 was reached that the development of bacteria was completely excluded. From these observations it is evident that the addition of perchloride of mercury to water in the proportion of 1 to 5,000 will certainly destroy every living organism in it. Such a solution may therefore be used to wash fresh wounds without any fear of infecting them either with septic or pathogenic organisms. A watery solution of this strength would, however, be quite inefficient as an antiseptic should it become mixed with any albuminous fluid, and consequently it is safer to use a solution of 1 in 2,000, or 1 in 1,000, for irrigating wounds during an operation, and the same strength is employed for cleaning the Surgeon's hands and for washing sponges. A solution of 1 in 500 may with safety be used to clean a foul abscess, but it must be applied with a sponge and the cavity afterwards dried with another sponge squeezed as dry as possible. For cleaning unbroken skin 1 in 500 may be used with impunity, but it must be remembered that, unlike carbolic acid, it will not act efficiently on a greasy skin. The grease must be removed by abundant washing with soap and hot water followed by a weak solution of ammonia. Solutions of corrosive sublimate prepared with ordinary water, deposit, after some time, an insoluble precipitate containing a considerable proportion of the mercury, amounting to more than 50 per cent. of that present if the water be very hard. If the solution is to be kept for any time, it is therefore usually recommended to prepare it with distilled water. Angerer of Munich has, however, shown that the precipitation may be prevented by the addition of an equal quantity of common salt to the perchloride. He recommends that the salt and sublimate should be fused together into small cakes containing enough to make a definite quantity, as a quart or more of the 1 in 1,000 solution. In this form the antiseptic can be readily carried in military surgery.

In preparing dressings to absorb the discharges of wounds or abscesses a larger proportion of sublimate must be added, for the reasons above given: the proportion most commonly adopted being about $\frac{1}{2}$ per cent. of the weight of the material used. For instance, to prepare gauze or wool, a solution is

made containing 1 part of perchloride of mercury, 450 of water, and 50 of glycerine. The wool or gauze is soaked in this for a few minutes, and then squeezed as dry as possible in a wringing-machine. It is next hung up to dry as far as the glycerine will permit, and is then ready for use. Jute, sphagnum moss, peat, sawdust, ashes, sand, and a variety of other absorbent substances may be prepared by being soaked in a 1 in 500 solution and dried. Small pads or cushions may be prepared by filling bags made of the gauze with any of the above materials. When applied as dressings, they are secured by bandages prepared in the same way. Bruns introduced a material made by grinding pine-wood, and known as "wood-wool," which from its softness, elasticity, and power of absorption makes an excellent dressing when prepared as above described.

Corrosive sublimate has proved a most efficient, useful, and economical antiseptic, but like all others it has its drawbacks. Amongst its advantages, especially in military practice, must be included the concentrated form in which it can be carried, and the ease with which almost any absorbent substance can be impregnated with it without the employment of any special apparatus. Like all other powerful antiseptics, however, it is irritating and poisonous, and as it possesses these properties in a higher degree than most others, a corresponding degree of caution is necessary in the preparation of the solutions and dressings and in their use. The maximum medicinal dose of the perchloride is contained in about $4\frac{1}{2}$ drachms of the 1 in 1000 solution, and it is evident, therefore, that in using such a preparation in a large hollow wound, a serous cavity, or a mucous canal, care must be taken that a poisonous dose be not left behind. Should such an accident happen, or should the patient be peculiarly susceptible to mercury, he is seized with pains in the belly, and diarrhoea with tenesmus and bloody motions. This may be followed by collapse and death, or the fatal result may be occasioned by exhaustion from constant diarrhoea. The colon and rectum, and sometimes the small intestine, in such cases are found to be acutely inflamed and superficially ulcerated. *Salivation has rarely been observed.* The number of cases on record in which fatal poisoning has followed the use of perchloride of mercury as an antiseptic is very considerable if those occurring in obstetric practice are included. In any case in which there is evident danger of such an accident, the strength of the solution should on no account exceed 1 in 2000.

Local irritation from sublimate dressings rarely occurs if the proportion of mercury is not too great. When it does happen, there may be redness and irritation or a superficial inflammation resembling eczema.

Sal Alembroth. a double chloride of mercury and ammonium, has been suggested by Lister as a substitute for the pure perchloride in preparing dressings. Its advantages are, that it is less irritating, and less prone to form a inert compound with albumen. Gauze impregnated with 1 per cent., and wool with 2 per cent., are the preparations that have been used. The only advantage which sal alembroth presents is its extreme solubility. It is very readily washed out of the dressing by an abundant discharge. The gauze and wool as sold are stained with an aniline blue to distinguish them.

Cyanide of Mercury and Zinc.—A combination of these cyanides of somewhat uncertain composition has been introduced as an antiseptic by Lister, and is now extensively used. It is insoluble in water, but

soluble in blood-serum in the proportion of 1 in 3000. It has little or no tendency to combine with albumen. The salt dissolved in serum has but feeble powers as a germicide if tested by its action on the spores of bacilli, but, on the other hand, its powers of inhibiting their growth are very considerable, and this is, from a practical point of view, all that is required for an antiseptic dressing. The preparation used is a gauze impregnated with the cyanides. It is a beautifully absorbent and a very efficient dressing. It is coloured mauve with rosolane, an aniline dye, which serves to fix the double salt in the gauze.

Creolin is a preparation of gas-tar closely resembling the original material in appearance and smell. It is said to be non-poisonous and free from carbolic acid. It is insoluble in water, but in the strength of 1 to 3 per cent. it forms an emulsion which can be used as a lotion to wash a wound or to moisten a dressing. The emulsion must be freshly prepared for each dressing, as it soon changes into a dirty brownish liquid on standing. It can also be used in the form of ointment. There is no doubt that an emulsion of creolin, from the strength 1 per cent. upwards, is a most efficient and unirritating antiseptic.

Chloride of Zinc.—The efficient strength of this antiseptic, which is the active principle of Burnett's fluid, is doubtful. According to Koch, a solution of about five grains to the ounce will not certainly kill non-spore-bearing organisms, and one of twenty grains to the ounce has no effect whatever on the spores of the *bacillus anthracis*. Its use in the treatment of wounds was introduced by Campbell De Morgan more than thirty years ago. It is usually employed in the strength of forty grains to the ounce of water. This solution produces a whitening of the surface, but the action is very superficial, and it does not cause the formation of a visible slough unless applied for some length of time; in fact, even in this strength, it does not prevent union by first intention. The whitened surface has been shown by experiment to form a remarkably efficient barrier to the absorption of the chemical products of putrefaction, and experience proves that decomposition of the discharges will not commence for about three days in a wound thus treated. It therefore forms a most useful application to wounds in which it is impossible to employ strict antiseptic treatment, such as those opening into the mouth, rectum, or bladder; for by the third day, when its influence seems to be exhausted, the opened lymph-spaces are so far closed by plastic exudation that the dangers of septic absorption are greatly diminished. It has no toxic effects when thus applied, but it must never be injected in this strength into any cavity or wound, as should any quantity be left behind, or should the lymph-spaces be injected, it may cause serious and extensive sloughing. It must be used only where the surface can be dried afterwards with a sponge.

Boric Acid was introduced into surgical practice by Lister. It is one of the less powerful, and at the same time one of the least irritating, of chemical antiseptics. It is soluble in 26 parts of cold water or in 3 of boiling water. Its efficient strength as an antiseptic is said to be about 1 in 130 or four grains to the ounce, but the concentrated cold solution or "*boric acid lotion*" is more commonly used. It is prepared by adding one ounce of the crystallised acid to a pint of boiling water, and afterwards allowing it to cool and the excess of the crystals to settle down; it forms a useful lotion for washing or irrigating wounds. Glycerine may be added to the lotion in the proportion of half a drachm to one ounce to prevent its drying when used, as to moisten a dressing.

Boric acid lint, which is prepared by dipping ordinary lint in a concentrated boiling solution of the acid and afterwards drying it, forms a useful application to wounds or granulating sores; and, if moistened with warm boric acid lotion, it may be applied with great advantage in the place of a poultice to sloughy and inflamed wounds. *Boric acid ointment* forms an excellent dressing for small wounds, such as those on the face, and for healthy granulating sores. It is now official. It should be spread on thin muslin and dipped in the boric acid lotion before being applied, after which it may be covered with cotton-wool and allowed to dry. It requires changing once or twice a day.

Sulphurous Acid is but little used as an antiseptic on account of its extremely unpleasant smell and its irritating properties.

Eucalyptus Oil is a powerful antiseptic, having a very fragrant camphoraceous smell; it is quite free from poisonous properties. It is practically insoluble in water, but readily dissolves in oil, paraffin, and spirit. It has been used in the form of eucalyptus gauze as a substitute for carbolic gauze in cases in which the patient showed signs of carbolic poisoning, or when the skin was irritated by the dressing, but, owing to the volatility of the oil, it soon deteriorates at the temperature of the body, and becomes useless after about twenty-four hours. For application to granulating sores an ointment composed of 2 parts paraffin, 2 vaseline, and 1 of eucalyptus oil will be found very useful. If the sore be foul some iodoform may be added in the proportion of one drachm to the ounce.

Iodine is one of the most powerful of all antiseptics. It has been recommended by Bryant as a lotion for washing wounds and sponges, in the strength of two drachms of the tincture to a pint of warm water; and in this strength it is an efficient antiseptic and very free from irritating properties.

Iodoform is an antiseptic of undoubted power which is used very largely in surgical practice. It is an iodine compound of methyl alcohol. It is sold in two forms—the precipitated, which is an extremely fine yellow powder; and the crystalline, composed of fine golden yellow crystals. The latter should always be used in wounds or on raw surfaces, as the finely divided particles of the precipitated form are too readily absorbed. Iodoform is insoluble in water but is readily soluble in chloroform and ether, sparingly so in alcohol, and very freely in oil. The preparations used in Surgery are the pure drug in crystals; *iodoform wool*, prepared by impregnating cotton-wool, deprived of its grease so as to render it absorbent, with 10 per cent. of the drug; *iodoform gauze* containing 20 per cent. of the drug; and *iodoform ointment*, made by mixing varying proportions of the crystals from one drachm upwards with one ounce of vaseline. The pure iodoform is specially applicable to wounds opening into cavities, such as those left by removal of the tongue or upper jaw. It may be sprinkled on the raw surface twice a day, and will completely prevent any unpleasant smell. The Germans have used it freely as an application directly to the raw surfaces of fresh wounds before closing them, and it has been found not to prevent union by first intention, but its use in this way is not to be recommended, as it is a needless introduction of a foreign body.

According to the ordinary modes of testing antiseptics by their power of destroying micro-organisms and their spores in laboratory experiments, iodoform is practically useless, but no Surgeon who has experience of its efficacy in operations on the mouth or rectum will doubt that it is one of our most

valuable means of preventing putrefaction and infection. This discrepancy is said to be explained by the fact that iodoform breaks up in the presence of pus, so that pure iodine is liberated. Protamines are also said to break up iodoform in the same way and at the same time to be themselves destroyed. Free iodine is well known to be one of the most powerful of all antiseptics, and thus the power of iodoform in checking decomposition and suppuration is fully explained. If much iodoform is used, iodine can always be detected in the urine in the form of iodides; but iodoform does not appear: this is further evidence of its breaking up, either in the wound or the blood.

Iodoform possesses very marked toxic properties, but the effect produced seems to depend to a great extent upon an idiosyncrasy on the part of the patient. The symptoms of iodoform poisoning are very various, and differ somewhat in children and adults. Amongst the most marked effects have been an elevation of temperature reaching 104° F., without other serious constitutional disturbance, and without any unhealthy appearances in the wound. Loss of appetite with progressive emaciation is common; the patient complaining that everything tastes and smells of iodoform. Vomiting, however, is not a frequent symptom. The effect on the pulse is often very marked, especially in children; the frequency is greatly increased, reaching 140 or even 180, and at the same time the force is correspondingly diminished. Its effects on the brain are often very serious: in some cases in adults it seems to have caused violent maniacal delirium, in others persistent drowsiness has been noted, with great mental depression. In children drowsiness is more common, and occasionally the symptoms may closely resemble those of tubercular meningitis. In other cases rapid collapse has followed the use of iodoform, for which no cause but the drug could be found. Many fatal cases have occurred in Germany; but the quantities applied have been in some cases so enormous that this is scarcely to be wondered at. As an external dressing to a wound, the edges of which have been brought accurately in contact, it has never been known to cause poisoning, though when applied on the raw surface left by a large burn it may give rise to some of the above-mentioned symptoms. The urine, in all cases of iodoform poisoning, has been found to contain iodine. The treatment consists in the immediate and complete removal of the drug, which will usually be followed by speedy disappearance of the symptoms. Iodoform very rarely causes any local irritation. It is said to have little or no power of destroying the virus of erysipelas.

Potassium permanganate, a solution of which is known as Condy's fluid, is a powerful oxidising agent. It possesses very active powers as a disinfectant, destroying the smell of decomposing matter even when used in very dilute solutions. According to Miquel, it prevents the growth of organisms when in the proportion of about two grains to the ounce of water. In the strength of about twenty grains to the ounce it will kill the spores of the *bacillus anthracis*, but such a solution cannot be used in surgery, as it stains everything with which it comes in contact a deep brown colour. The weaker solution forms a valuable lotion or wash for foul wounds. It possesses practically no toxic properties.

Aluminium acetate, in the strength of about ten grains to the ounce, has been recommended as a non-poisonous antiseptic by Maas, and has been extensively used in Germany.

Both the **acetate** and the **subacetate of lead** possess antiseptic properties.

and to this they partly owe the reputation for preventing inflammation in wounds.

Benzoic acid possesses extremely powerful antiseptic properties, but has not been used pure in the treatment of wounds. It forms an important constituent of Compound Tincture of Benzoin, Friar's Balsam, or Wound Balsam, which was formerly extensively employed as an external application to wounds, and is still sometimes applied to compound fractures.

Turpentine was, in former times, a constituent of almost all salves for wounds, and doubtless did excellent service as an antiseptic. At the present time it is scarcely ever used. A highly refined form is sold under the name of *terebene*, which, dissolved in olive oil in the proportion of 1 to 5, forms a useful antiseptic application.

Thymol is the aromatic principle of thyme. It is said to be an efficient antiseptic if dissolved in water in the proportion of 1 in 1000. It is but little irritating and is not poisonous; but it presents few other advantages, and is rarely used except for washing out a cavity, as the rectum, from which carbolic acid might be absorbed in dangerous quantities if injected.

Glycerine possesses feeble antiseptic properties, the efficient strength with water being, according to Miquel, 1 in 4. It is chiefly useful as an addition to boric or carbolic lotions, to prevent their drying too quickly.

Alcohol.—According to Miquel, the efficient antiseptic strength of an alcoholic lotion is 1 in 10, that is to say, two ounces of absolute alcohol or four of proof spirit in a pint. Absolute alcohol has no influence whatever on the spores of pathogenic bacilli. Alcohol is but little used in surgery as an antiseptic, as it evaporates too rapidly, but it may be employed as a wash for wounds or for the hands and instruments if none more efficient is at hand.

OTHER METHODS OF PREVENTIVE TREATMENT.—Amongst the most useful means of preventing inflammation is the application of **cold**. This causes contraction of the vessels, and thus limits exudation and prevents swelling and tension. The cold should not be so intense as to lower the vitality of the injured part, or it may cause the very mischief it is intended to prevent. For this reason it is of doubtful utility in all superficial injuries or in cutting short superficial inflammations, while it is of undoubted use when applied to the skin in sprains and other injuries of joints, or in injuries of the brain. In the latter cases it causes a contraction of the vessels without actually chilling the injured part. Cold is of no use in checking infective inflammations of any kind, its chief value being in limiting the simple traumatic inflammation following subcutaneous injuries. Its application must be *continuous*, or the periods of hyperemia in the intervals between the cold applications will undo any good that may have resulted from the cooling. If the injury be not very severe, lint dipped in cold water, frequently renewed, may be applied; or, if the skin be unbroken, an evaporating anesthetic lotion may be used. Should a joint be severely injured, cold irrigation will be a preferable mode of applying cold. This may be done by suspending over the part a large wide-mouthed bottle full of water, in which a few pieces of ice may be put; one end of a skein of cotton, well wetted, is then allowed to hang in the water, whilst the other end is brought over the side of the bottle. Thus, acting as a siphon, causes a continual dropping upon the part to which the cold is to be applied.

But the direct application of pounded ice in a bladder or thin rubber bag is the most effectual means of applying cold, when it is intended that its effects shall penetrate deeply, as in an injured joint, spine, or head.

Another very efficient mode of applying cold is to surround the part with a coil of india-rubber tubing through which a stream of iced water is allowed slowly to flow from a reservoir placed above the bed. This method was introduced by Otis as a mode of applying cold to the genital organs, and for this purpose it is very efficient. When applied to the head or to a limb, the weight of the part is apt to compress the tube and arrest the flow. To overcome this difficulty, the apparatus known as "**Leiter's tubes**," made of soft metal which can be accurately applied to any part of the body, has lately been introduced. In using this the water must not be iced, as the greater conducting power of the metal renders this not only unnecessary but dangerous.

The application of a cold **Lead Lotion** acts as a powerful local sedative, and tends greatly to restrain local inflammation.

Absolute rest of the parts is an essential element in the preventive treatment of inflammation. Rest as to movement or use is imperative. An injured joint should be placed at rest on a splint; light should be excluded from an injured eye.

At the same time all constitutional disturbance must be prevented by a moderate and well-chosen diet, by repose of body, by regulation of the action of the bowels, and by careful attention to the hygienic surroundings of the patient.

CURATIVE TREATMENT OF ACUTE INFLAMMATION.—In the curative treatment of inflammation the first object of the Surgeon is, if possible, to remove the cause, and to exclude every accessory source of irritation from the inflamed part. Thus, if there be an accumulation of septic matter, this must be removed, and the septic process checked by the use of antiseptics. If a foreign body be lodged in the flesh it must be extracted, and complete anatomical and physiological rest of the inflamed part must be ensured. At the same time the afflux of blood must, if possible, be kept within bounds, and blood-pressure reduced so as to limit the exudation and reduce tension. In attending these objects constitutional and local means are made use of.

LOCAL TREATMENT OF ACUTE INFLAMMATION.—Position and Rest.—The first step in the treatment of an inflamed part is to put it at perfect rest. All motion and use must be prevented, and, if necessary, restrained by splints and other appliances. If possible, the inflamed part should be elevated to a level with, or above, the rest of the body, in order to facilitate the return of blood, and thus to diminish congestion and reduce the blood-pressure in it, and thus lessen exudation and tension.

Cold and Heat are both used in the treatment of acute inflammation. The use of **Cold** in the prevention of inflammation has already been described (p. 213). When inflammation is fully established with its cardinal symptoms of redness, swelling, heat, and pain, cold should never be applied; as, although it may lead to a diminished flow of blood to the part by causing contraction of the arteries, it tends still further to lower the vitality of the affected tissues, and thus to increase the adhesion of the corpuscles and the retardation of the flow, till stasis, followed by death of the part, may result. Cold should never be had recourse to when suppuration is threatening or has set in; still less should it be employed when there is a tendency to mortification. The modes of applying cold have already been described (p. 213).

Warmth and moisture, conjoined, are of the utmost service in the treatment of inflammation during the height of that process—during that period when cold applications are not admissible. By these means the vessels are dilated to the fullest extent and the tendency to stasis diminished. The warmth tends also to hasten the return of vitality in the damaged area, if that be possible, and is, therefore, especially valuable in all cases in which there is a tendency to sloughing. The exudation from the distended vessels is increased, and it is believed that this tends to carry the migrated corpuscles out of the inflamed part into the lymphatics in those cases in which the irritant causing the inflammation is not of sufficient intensity to give rise to suppuration. It may also, by stimulating the activity of the migrated leucocytes, aid them in resisting the invasion of micro-organisms. Should suppuration be inevitable, warmth hastens the process by increasing the exudation and migration. Warmth and moisture, by causing relaxation of the parts, diminish tension and thus relieve pain.

When abscess threatens, and the skin is not broken, nothing affords so much relief as a well-made **linseed-meal poultice**. To make this smooth and soft, the meal must be gradually added to the proper amount of boiling water, being vigorously stirred at the same time. If the water be added to the meal, the mass is apt to become lumpy. It must be spread, not too thickly, on a piece of linen-rag, and applied as hot as the patient can bear it. It is better to use meal from which the oil has not been expressed, or to add to the ordinary linseed meal a small quantity of olive oil, which prevents its drying and sticking to the skin. But, useful as poultices are when the skin is unbroken, they are most objectionable when applied to a wound, ulcer, or granulating surface. Then they merely encourage putrefaction. In such cases **wet dressing**, consisting of a double or triple layer of common, or better boric, lint, moistened with a hot solution of boric acid, may be applied and covered with oiled silk extending half an inch to an inch beyond it on all sides. This may be covered with a thick layer of cotton-wool secured by a bandage. By these means we obtain an application which is cleaner and lighter than a poultice, and which retains its heat equally long. Another excellent substitute for a poultice is a sheet of salicylic wool (4 per cent.) about one inch thick, moistened with boiling water and covered with oiled silk and dry cotton-wool. This is also a most efficient antiseptic application.

Fomentations of warm water, or of decoction of poppy and camomile flowers, applied by means of flannels wrung out of these liquids, and applied hot, are very useful in extensive superficial inflammations. The flannels should be well covered with oiled silk or rubber cloth, so as to retain the heat and to prevent evaporation. Spongio-piline may be used as a substitute for flannel in cases in which the surface is unbroken.

Dry cotton-wool heated before a fire, applied warm, and covered with a large sheet of oiled silk, may sometimes be conveniently substituted for a fomentation. The watery vapour given off from the skin being enclosed by the oiled silk forms a sort of warm vapour bath for the affected part. Dry heat in the form of flannels, or bags of bran toasted before the fire, or heated in an oven, are often convenient applications, especially for the head or abdomen.

Belladonna, applied externally, sometimes exercises a very distinct influence over superficial inflammations of an acute and spreading character. It is

supposed to act partly by causing contraction of the small arteries by its direct action on the vaso-motor nerves, and partly by its sedative effect on the cutaneous sensory nerves, stimulation of which, as we have before seen, causes by reflex action a dilatation of the vessels in the area irritated. It is best applied, in conjunction with warmth and moisture, as a paint composed of equal parts of the extract and of glycerine, which may be smeared on the inflamed part and covered with cotton-wool, or hot fomentations. There is no danger of belladonna poisoning, even when large surfaces are painted with the extract and glycerine. I have frequently painted the whole arm in this way without any unpleasant effect; and the most I have ever noticed has been a little dryness of the throat after some days' use of the drug. The belladonna and glycerine must be carefully kept out of the way of children, as its taste is not unpleasant, and they are very likely to eat it by mistake for treacle. Two such cases have been admitted into University College Hospital, both of which fortunately recovered.

In superficial inflammations **Acetate of Lead** 4 grs., and laudanum 3 grs., to one ounce of water, diluted with an equal quantity of boiling water and applied hot on lint, will often be found a very useful application.

Local Blood-letting is an efficient means of lessening the congestion of an inflamed part, as by it in some cases we take blood directly from the distended vessels. It does not always act, however, quite so simply as this. In no disease is the benefit of local blood-letting more marked than in acute inflammation of the middle ear, and yet in this case we draw the blood from the cutaneous vessels of the mastoid process. In acute orchitis relief is often given by puncturing the distended veins of the scrotum, which have no direct connection with the swollen gland. In these cases the relief is probably due to a reflex contraction of the arteries leading to the inflamed part. The amount of blood taken in local blood-letting is not sufficient to have any influence on the general circulation.

Blood may be taken locally by *punctures, scarifications, or incisions*, or by *leeching or cupping*.

Punctures, scarifications, and incisions can be practised only in inflammation of the cutaneous and exposed mucous surfaces. They constitute a very efficient means of relieving the part, as not only is blood removed, but an exit is afforded for effused matters; tension is consequently materially lessened, and any tendency to sloughing diminished. There is no doubt also that in some infective inflammations they allow the fluids which are charged with the noxious products of the growth of the pathogenic organism to escape externally, instead of returning to the blood-stream, and thus materially relieve the constitutional disturbance. **Punctures** should be made with a fine lancet, in parallel rows over the inflamed surface, and should not exceed a quarter of an inch in depth. **Scarifications** are small and short incisions. They may be made across the congested vessels, which will bleed freely, as in the relief of a chemosis of the conjunctiva. A modification of puncture is sometimes practised by opening the veins in the neighbourhood of the inflamed part at several points, as in puncture of the scrotal veins, for inflammation of the testis.

When **incisions** are required they should be so arranged as to afford the greatest possible relief to the tension whilst doing the least possible mischief to the part incised. Their length and their depth must vary

according to the seat of the inflammation. Care must be taken as far as possible not to wound superficial arteries or veins of sufficient size to bleed dangerously.

Leeches may be applied to the neighbourhood of inflamed parts, but never upon the inflamed surface itself, as their bites irritate. There are certain situations in which leeches should not be placed, as over a large subcutaneous vein, or in regions where there is much loose areolar tissue, as the scrotum or eyelids, lest troublesome hæmorrhage or ecchymosis occur. So, also, they should not be applied near a specific ulcer, lest the bites become inoculated by the discharge. Should it be thought desirable to produce some constitutional effect, the bleeding may be encouraged by poultices or fomentations after the animal has dropped off. In this way from half an ounce to an ounce of blood may be taken by each leech. Owing to the fact that the leech secretes a material which prevents the coagulation of the blood, the hæmorrhage, which usually ceases spontaneously soon after the leech is removed, may continue for some time, and be difficult to arrest. Continuous pressure, the application of matteo, or powdered alum, may then be tried, and if these fail—as may happen in some situations where pressure cannot be conveniently applied, as on the neck and abdomen, particularly in young people—a piece of nitrate of silver scraped to a point, or a heated wire introduced into the bite, previously wiped dry, or a needle transfixing the edges of the bite with a twisted suture over and around it, may be required.

Cupping may be either “wet” or “dry.” Dry cupping consists in the application of the cupping-glasses to the skin without making any previous scarifications. It is a means of causing a determination of blood to the surface for the purpose of diminishing the flow to an internal organ. Thus in congestion of the kidneys following an operation on the urethra or bladder, dry cupping in the loins is often of use. The instruments required are a spirit lamp with a large flame, and the cupping-glasses. These are made of thick glass and are dome-shaped with smoothly-ground edges. The operation consists merely in rarefying the air in the cupping-glass by means of the flame of the spirit lamp, and instantly applying the glass firmly and evenly to the skin. The intention is not to heat the glass but the air contained in it, and in fact to a great extent to replace the air by the products of combustion of the flame of the lamp. It is for this reason that a large flame completely filling the glass should be used. If the operation be properly performed the rim of the glass will be marked by a bruise due to the rupture of the capillary vessels in the area included in the vacuum.

In wet cupping the glass is applied in the same way over a number of superficial incisions which are made instantaneously by the “scarificator,” an instrument provided with a number of parallel knives worked by a spring and released by a trigger. The quantity of blood extracted is regulated by the size of the glass, and the flow from the superficial wound ceases the moment it is removed. Cupping cannot be employed upon the inflamed surface itself, as it would be too painful, and is chiefly applicable to internal inflammations. As the scars made by the scarificators continue through life, cupping should not be practised upon exposed surfaces.

A modified form of cupping in which the vacuum is made by withdrawing a piston in a glass tube, or the *artificial leech*, as it is called, is not uncommonly used in ophthalmic practice.

Local blood-letting is now perhaps less used than it deserves to be. A few leeches give almost immediate relief to pain in many inflammations of the eye and middle ear and in simple inflammations of serous and synovial membranes. In acute infective inflammations they are evidently useless. They cannot arrest the growth of the micro-organisms which are causing the disease. It is therefore absurd to imagine that septic peritonitis following a wound of the abdomen can be influenced in any way by a handful of leeches drawing blood from the abdominal wall.

Cutting off the Supply of Blood from the inflamed part by the ligation of the main artery leading to it has been adopted in some cases. Thus, in acute inflammation of a joint, the main artery of the limb has been tied—the femoral, for instance, in inflammation of the knee-joint—but by most Surgeons the remedy would be considered worse than the disease.

Vanzetti recommended digital pressure on the arteries in inflammation. He has, for instance, related a case of severe acute inflammation of the hand, relieved by twenty-four hours' continuous pressure on the brachial artery. Nendorfer speaks highly of the proceeding, which he regards as surpassing all others in efficacy. It is applicable to inflammation of any part of which the artery is within reach.

CONSTITUTIONAL TREATMENT OF INFLAMMATION.—In the constitutional treatment of inflammation the Surgeon has various objects in view and must be influenced in the means he adopts by the general condition of the patient. In some cases it is his object to diminish the blood-pressure, in the hope of limiting exudation, by means calculated to reduce the force of the heart's action, as by general blood-letting or by the use of certain drugs. In other cases his chief object is to reduce the fever, especially when it assumes the *athenic* type (p. 199), and when the opposite condition is met with his attention is chiefly directed to supporting the strength of the patient.

One of the most powerful means we possess of reducing the blood-pressure is **General Blood-letting**. When it was believed that acute inflammation was an active process which could be cut short by means calculated to reduce the strength of the patient, or, as it was termed, by **antiphlogistic treatment**, bleeding was the routine practice in all acute inflammatory diseases unless the age or weakness of the patient contra-indicated it. Now that we have a better knowledge of the nature and causes of inflammation, bleeding in surgical cases is almost completely abandoned. No one believes that the invasion of a pathogenic organism or putrefaction in a wound or cavity will be controlled in any way by bleeding; in fact, such treatment can only make the patient less able to resist the effects of the organisms and their products. The only surgical conditions in which blood-letting is of any service are: first, in certain cases of simple traumatic inflammation of the brain following laceration, in which the swelling of the cerebral substance is causing dangerous symptoms (see Chap. XXIV. Laceration of the Brain); secondly, in some cases of injury of the chest in which, owing to interference with respiration, the right side of the heart is overloaded with blood; thirdly, it is possibly useful in certain cases of internal hæmorrhage; and lastly, in some cases of internal aneurism. It will be observed that, only in the first of these is blood-letting used with the intention of limiting inflammatory exudation. The influence produced by blood-letting is judged of by the effect on the pulse, which should become softer and less tense. The frequency is not so much affected and

may even be reduced. It is always desirable to produce the necessary effect with the least possible loss of blood ; hence the blood should be taken from a large orifice, the patient sitting upright. In repeating the venesection, we must be guided by the impression that has been made upon the disease, and by the state of the pulse. In former times, blood-letting from the temporal artery and the external jugular vein was sometimes practised ; but, at the present day, blood is scarcely ever taken from any vessel but the median basilic vein at the bend of the elbow. The operation is thus performed : the region of the vein having been carefully cleaned with some efficient antiseptic and the patient being in a sitting posture, a tape or a piece of bandage is bound round the arm about midway between the shoulder and the elbow, with sufficient firmness to obstruct the return of blood through the veins, and yet not to interfere with the flow through the artery. When the limb below the bandage is fully distended with blood, the operator selects the most prominent vein at the bend of the elbow, which will almost invariably be the median basilic, and compresses it with his thumb *below* the point at which it is intended to open it ; this serves the double purpose of steadying the vein and preventing a premature escape of blood. He then takes the lancet, or any other small sharp-pointed cutting instrument if a lancet be not at hand, and holding it by the blade between his forefinger and thumb, while he steadies his hand by resting the other fingers on the arm of the patient, he divides the skin and opens the vessel by a single incision about one-third of an inch in length, carried obliquely across the vein and dividing its anterior wall. He then takes a graduated vessel, and, holding it in such a position as to catch the blood, he removes his thumb from the vein, and allows the proper amount to escape. During the operation the patient should hold some round body in his hand, which he can grasp firmly at intervals ; by this means the blood from the deep veins is driven out from amongst the muscles into the median by the communicating branch which enters it just before its bifurcation. As soon as a sufficient quantity of blood is drawn, the constricting band on the arm is relaxed : an antiseptic dressing of some kind is applied over the wound and secured by a few turns of a figure-of-8 bandage. The only accident that can happen during the operation is a wound of the brachial artery, which usually lies immediately beneath the median basilic vein near the point selected for bleeding. This is avoided by holding the blade of the lancet short and firmly, and supporting the back of the three inner fingers on the patient's arm : while by a movement of extension of the wrist, the point of the instrument is made to move in a segment of a circle, and so to open the prominent vein without any risk of penetrating more deeply than is intended. If from inadvertence the patient be bled in the recumbent position, a greater quantity of blood may be removed than is intended before the effect on the pulse is produced.

The only complication to be feared after the operation is septic inflammation of the vein, and although this is very rare it is sufficiently frequent to necessitate the careful use of antiseptics.

Bleeding from the external jugular vein should never be performed, as it is accompanied by the danger of entrance of air, and the effect produced differs in no respect from that of bleeding from the arm.

In inflammations of the head and chest a good effect may often be produced by *diverting the blood as much as possible to the lower extremities* by placing

them in hot water or by the application of elastic bandages in such a way as to engorge the limbs with blood.

We must in all cases endeavour to *set the secretions free*, and in this way to clear the blood of the morbid products accumulated in it. If we can obtain a copious bilious evacuation from the bowels or an abundant acid perspiration from the skin, or a copious discharge of urine, we shall diminish the constitutional disturbance and mitigate, if not cut short, the local process. With these objects in view, purgatives, diaphoretics, and diuretics are to be administered.

Purgatives, by causing dilatation of the vessels of the alimentary canal, reduce the blood-pressure in other parts, and this effect is still further increased by the diminution they cause in the general mass of the circulating fluid. Moreover, they clear the intestinal canal, and thus favour digestion and assimilation of food. From the frequency with which diarrhoea is associated with unhealthy inflammatory processes, it seems probable that the intestinal tract forms an important channel for the elimination of the products of such inflammations from the blood, and the necessity of maintaining a proper action of the bowels would thus be explained. Experience teaches us also that in inflammatory affections constipation always aggravates the elevation of temperature, and a brisk purgative will often bring it down one or two degrees. This is especially the case with children. Purgatives should, therefore, always be given early, except in some special cases of acute inflammation of the abdominal organs. In general, it will be found most advantageous to administer a mercurial, followed by a brisk saline purge; and this should be repeated from time to time during the progress of the case.

Diuretics and Diaphoretics are of much use when fever forms a marked feature of the case, and they should then be administered frequently during the day. Free perspiration lowers the temperature by increasing the loss of heat from the surface of the body and the dilatation of the cutaneous vessels tends to diminish the blood-pressure in internal parts. Both the skin and the kidneys also take an important part in the elimination of the products of the increased tissue-change which forms an essential feature in the febrile process; and, unless both perform their functions properly, these products may accumulate to a dangerous extent. The diaphoretics and diuretics most commonly used are citrate of potash, acetate of ammonia and nitrate of potash. *Antimony* in small and repeated doses was formerly much used partly with the intention of reducing the force of the heart's action and partly to induce sweating, when the skin was hot and dry. It may be given in the form of antimonial wine conjoined with the salines above mentioned, or as James's powder combined with Dover's powder, but if it be pushed too far, so as to induce nausea, it may seriously depress action of the heart, and consequently its effects must always be carefully watched.

Aconite in small doses frequently repeated—one minim of the tincture every half hour for four hours and then every hour—exercises a most marked influence on simple inflammatory fever with high temperature, but with no visceral complications. It lowers the force and frequency of the pulse and produces speedy and copious sweating, to the infinite relief of the patient.

Mercury was formerly much used, especially in acute inflammations of serous and fibrous membranes, not as a purgative but as an alterative, led to a point just short of affecting the gums. It is not now given

in this way in acute inflammation. As a purgative its value cannot be over-rated.

Opium is of essential service in allaying the pain and irritability that often accompany inflammation, especially in many affections of the bones and joints. Dover's powder is of especial value in this respect, and alone or combined with James's powder, forms one of the most powerful diaphoretics we possess.

Treatment of Inflammatory Fever.—The treatment of fever in surgical and medical cases is entirely different. The fever in the vast majority of surgical cases is due to the entrance into the blood-stream of some pyrogenic substance derived from a local source; such as an unhealthy wound, an unopened abscess, &c. In the treatment of the fever in such cases it is the duty of the Surgeon to seek the source of the pyrogenic material and to cut off the supply, as by opening the abscess, cleaning the foul wound or cavity, &c. In medicine unfortunately the physician is as a rule unable to do this, and consequently has to fall back on drugs, a practice which the Surgeon should only adopt as a last resource.

The treatment of fever must necessarily vary with the type it assumes, whether it is *sthenic* or *asthenic* (p. 199). In all forms the patient must be put to bed and kept warm and quiet. The diet must be light but nutritious; beef-tea, veal, mutton, or chicken broth, bread and farinaceous puddings being the chief constituents. During high fever the patient has no appetite for solid food, nor could he digest it, but eggs and milk can often be taken. The eggs must be raw or very lightly boiled, and may be beaten up with the beef-tea or milk. Milk should always be boiled, and it will be found in many cases very useful to add a very small quantity of arrow-root, which makes the curd less lumpy in the stomach and more easy of digestion. The thirst from which the patient suffers is often best relieved by lemon-juice and soda-water with little or no sugar, or by dilute phosphoric acid in the proportion of about one drachm to one pint of water sipped occasionally, or aromatic sulphuric acid in about the same dose. The patient's mouth should always be carefully cleaned several times a day with an antiseptic fluid of some kind, such as peppermint water, spirits of juniper largely diluted with water, boric acid lotion, Condy's fluid, &c. The foul mouth in fever is one of the patient's greatest sources of discomfort. In order to keep the skin clean and active the body should be daily washed with warm water, only a small part being exposed at one time, so as to avoid cold.

If the fever assume the *sthenic form*, with a full and bounding pulse and a high temperature with headache, and possibly delirium, as a rule no alcohol is required, although sometimes it may help in reducing the temperature and promoting sleep. The patient's bowels must be kept open and diaphoretics administered as already described. It is in these cases that specific drugs may be used, supposing the Surgeon cannot arrest the fever by cutting off the supply of the pyrogenic substance entering the blood-stream. The antipyretics most commonly employed are quinine in large doses, salicylate of soda, and the various coal-tar derivatives known as antipyrin, antifebrin, and phenacetin. Of these, quinine and salicylate of soda have been credited with some power of destroying, or at least inhibiting, the growth of micro-organisms in the body, but the evidence as to this is not satisfactory. All except quinine are extremely depressing drugs, causing profuse perspiration, and must be administered with

great caution, especially in cases of severe surgical injury. Phenacetin is said to be least likely to be followed by unpleasant consequences. Of all these drugs, quinine is the most practically useful in surgical cases, and no artificial product has yet been found to equal it.

An ice-cap to the head will be found of great use in many cases. It helps to reduce the temperature and relieves the headache. In extreme cases of hyperpyrexia, which are rare in surgical practice, wet-packing or cold baths may be employed to reduce the temperature, should their use not be contra-indicated by the nature of the injury or by some visceral complication.

When the fever assumes the *asthenic type* in a surgical case, either from the beginning or as a sequel of the *sthenic form*, it is always due to some general infective process or to absorption of septic matter. This form is predisposed to by the broken state of the constitution, from drinking, poverty and foul air, so commonly met with in the patients in a London hospital. In such cases any so-called antiphlogistic treatment is evidently out of place, and all depressing antipyretics should be avoided. The bowels must be cleared out and diaphoretic salines may be given. Carbonate of ammonia in doses of from three to five grains in decoction of cinchona is often useful. Quinine in five-grain doses, repeated four times a day, may be of use, especially in the fever of pyæmia and septicæmia. The diet must be as nourishing as the patient can take, and of the character before described. It is in this form of fever that alcohol is of the greatest use. This is not the place to enter into a discussion of the much-disputed question whether alcohol can act as a food. There is no doubt that it enters the blood unaltered, and that in some way it disappears from the body when the amount given is moderate in amount. When an excessive quantity is administered, it appears unchanged in the breath, sweat and urine. Doubts have been raised as to its combustion in the body because there is no increase in the carbon dioxide given off by the respiration after its administration. No other mode of elimination has, however, been demonstrated, and it is quite reasonable to suppose that the absence of any increase in the carbon dioxide expired may be due to the diminished oxidation of other substances in the body during the time that the alcohol is being consumed. One thing, however, is quite certain, and that is, that if we desire alcohol to act as a *food only* in producing energy by combustion, it must be given in very small doses, such as a teaspoonful of brandy, very frequently repeated, as there is no mechanism by which it can be stored in the body. If half an ounce of strong spirit be given in a single dose, some is lost by the breath and skin, and the heart is stimulated to excessive action, thus wasting the force it is our desire to conserve. On the other hand, it is sometimes our object to "whip up" the heart, especially when there is a tendency to passive congestion and stasis, as in hypostatic pneumonia; in that case a periodical large dose of alcohol, or perhaps of ether, will produce the desired effect.

The proper use of alcoholic stimulants in fever is a most difficult problem. The popular notion that alcohol "gives strength," and that the more you can give to an exhausted patient the better, has not one atom of evidence to support it. It is very rarely that a patient is really benefited by more than eight ounces of good brandy per diem, and care must be taken that it is not given in such an amount as to extinguish whatever appetite may

remain for ordinary food. When the patient can take it, porter or stout may be given, as they contain much genuine food in addition to the alcohol. When the patient is recovering, alcoholic stimulants with the meals often increase the enjoyment of food and promote digestion, especially in those accustomed to their use.

The asthenic type of fever, formerly so common, is not now so often met with in hospital practice. In a certain proportion of cases the constitutional state of the patient is such that any inflammatory process will certainly assume this type, but in the majority of cases the special constitutional state is secondary to an unhealthy septic or infective process going on at the seat of inflammation. By the prevention of these unhealthy processes by the modern treatment of wounds, and by the improvement of the general hygienic conditions of our hospitals, much has been done to prevent the occurrence of the worst form of asthenic inflammatory fever.

Chronic Inflammation.—The foregoing description has referred solely to acute inflammation, and it now remains to give a brief summary of the distinctive characters of the chronic form of the process.

It is commonly said that chronic inflammation, although differing from the acute form in its course, symptoms and effect, is but a modification of the same process. This is no doubt true of many forms between which and the acute process no sharp line can be drawn, but a large number of pathological changes which are described as chronic inflammation differ so widely from the acute process that it is difficult to see any point of analogy between them. In acute inflammation the original tissues are passive during the acute stage of the process, the cells infiltrating the part being all migrated leucocytes, and it is not till the tissues are recovering from the damage they have suffered that proliferation of the original cells commences. In many pathological processes classed under the heading of Chronic Inflammation new growth from the original tissues forms the sole phenomenon, and there is no evidence of migration of leucocytes at any stage. Between these two extremes every gradation is met with, and it is common to find migration of leucocytes and destruction of tissue going on side by side with proliferation and growth, and the two processes are often so intermixed that it is often impossible to determine, with any degree of certainty, the origin of a large proportion of the new cells infiltrating a chronically inflamed area. This combination of the two processes is due to the fact that chronic inflammation is the result of irritation of a low and frequently varying degree of intensity acting for a prolonged period of time, and, as has already been pointed out, the same cause which, acting intensely, may give rise to acute inflammation and even to death, acting less powerfully may stimulate the original cells of the part to proliferation and growth. In no chronic inflammatory process is there any permanent increase in the more highly differentiated structures. For example, in chronic inflammation of a gland, the glandular epithelium degenerates, while the interstitial tissue increases, and in the central nervous system the nerve-cells degenerate as the connective tissue increases. Surface epithelium such as that of the skin or mucous membrane frequently hypertrophies in chronic inflammatory processes, and in the growth of new connective tissue new vessels are often formed, but the new connective tissue as a rule becomes dense and scarlike, and compresses the higher tissues amongst which it is developed. It is always devoid of new elastic tissue. In all chronic inflammations any new tissue that forms

is of low vitality and readily degenerates, and the chronic process may often be intensified to the acute from a comparatively slight increase in the local irritation.

Widely, therefore, as chronic inflammation may differ from the acute process, there are points in which an analogy may be traced between them. In acute inflammation the essential features are a diminution of the vital activity of the tissues, and of the walls of the vessels consequent upon some injurious influence acting upon them. This is followed by dilatation of the vessels with exudation of almost pure blood-plasma, and migration of leucocytes which infiltrate the damaged area, while at the same time changes of a degenerative or destructive character take place in the original tissues of the part. In chronic inflammation all these phenomena may occur, but they are less strongly marked. They may conveniently be considered in the same order as in the acute process.

The dilatation of the vessels and afflux of blood are much less. The chronic distension, however, lasting as it may do for an indefinite period, leads to a permanent loss of tone and dilatation, especially in the small veins, which, in chronically inflamed parts, can often be seen clearly with the naked eye. The relaxation of the arteries is less complete, and there is often a tendency to slackened circulation. The redness, when present in chronic inflammation, is therefore as a rule more dusky than in the acute form. The whole process being due to a slighter degree of damage to the tissues, there is not the same impairment of vitality in the walls of the vessels, and consequently the tendency of the corpuscles to adhere to the vessels and retard the flow is little marked. Migration when it does occur is usually less abundant, and probably is influenced by the conditions described on p. 161. The vessels in most cases still retain to some extent their selective influence on what passes through their walls, and the exudation in chronic inflammations is less rich in albumen and often not spontaneously coagulable. Thus in chronic inflammations of serous or synovial cavities, we frequently find them distended with a fluid of considerably lower specific gravity than that of the liquor sanguinis, and not possessing the power of spontaneous coagulation. In those chronic inflammations which are partly caused by prolonged passive congestion, red corpuscles are frequently found outside the vessels.

The tissues of a part affected by chronic inflammation become, as in the acute process, crowded with new cells, the probable origin of which has already been mentioned. These new cells show the same phagocytic properties as those met with in acute inflammation. They take an active part in the destruction and absorption of dead or degenerating tissues, as, for example, the osteoblasts in chronic inflammation of bone, and in infective inflammations caused by invading organisms they are often found to have surrounded the pathogenic fungi, or to have taken them into their substance, as is seen in the giant cells of tubercle.

The new cells produced in chronic inflammation undergo a variety of changes according to circumstances. If the part recovers, they may, as in acute inflammation, disappear, probably disintegrating or being absorbed, or possibly, if still possessing amoeboid properties, wandering away into the lymphatics. It is rare, however, for perfect recovery to follow chronic inflammation; most commonly some thickening or induration from newly-formed fibrous tissue is left behind.

In other cases the cells may go on proliferating, slowly destroying or dis-

placing the surrounding tissues till they form a mass, often of considerable size, as in some forms of chronic inflammation of the synovial membranes of joints; in these masses of cells new vessels are formed, but the vascularisation of the new growth is always more or less imperfect, so that degenerative changes early set in for want of sufficient supply of nutriment. Thus, in chronic tuberculous inflammation of joints, we may find, replacing the synovial membrane, a soft pulpy mass of tissue, perhaps an inch in thickness. The layer of this, in nearest relation to the vessels of the surrounding healthy structures, is moderately supplied with new vessels, and presents the ordinary appearances of healthy granulation-tissue; next to this is a layer containing few vessels, and lastly, we find a layer in which the cells have perished from want of blood supply. If they are still recognisable as cells, they are withered and shrunken and filled with fat-granules; but usually they are in part at least reduced to a granular mass, in which no individual elements are any longer to be seen. This change is known as "*caseation*." The fatty layer may soften and break down into a fluid, which somewhat resembles pus in appearance, but on microscopic examination is found to contain few, if any, pus-cells. The collection of fluid thus formed is a *chronic* or *cold abscess*.

Another fate that may befall the accumulations of cells formed as a consequence of chronic inflammation is, that after undergoing complete fatty degeneration, the mass so formed may become dry and cheesy by the absorption of its fluids. The dry cheesy masses thus formed may remain in this state for an indefinite period, but at any time they may soften from causes as yet but imperfectly understood. In the process of softening, the cheesy matter undergoes chemical changes which give it irritating properties; and, as the result of this, inflammation of a more acute character with suppuration may be set up, leading to ulceration in the tissues surrounding it, or to the formation of an abscess which finds its way to the surface, and thus the caseous matter may be eliminated from the body.

Another change, the reverse of softening, may take place, when the mass is of small size; it may shrink and dry up more completely, and lime-salts may be deposited in it, forming a chalky concretion, which remains permanently unchangeable and harmless. Chronic inflammation, with caseation of the inflammatory products often followed by softening, are of frequent occurrence in lymphatic glands, bones, and the subcutaneous tissue; calcification is occasionally met with in bone, and is very common in the lymphatic glands. Both processes are very frequently the result of tubercle, but are by no means exclusively caused by it. Both caseation and calcification are met with in chronic endarteritis: in the syphilitic gumma a fatty degeneration closely resembling the caseation of tubercle occurs; typical calcification is met with in the chronic inflammatory tissue surrounding a hydatid cyst or enclosing a trichina spiralis, and many other examples might be given.

Chronic inflammation gives rise to yet another change, differing essentially from those already described, viz. to an overgrowth of the connective-tissue of the affected part, or fibrous hyperplasia. In many organs and tissues the new fibrous tissue causes an induration to which the term "*sclerosis*" is applied. This forms the most marked feature of many forms of chronic inflammation, as in chronic interstitial inflammation of glandular organs, chronic osteitis and periostitis, chronic arteritis, and chronic inflammatory affections of the skin. Many of these affections are so far removed from

inflammation in their clinical features, that some pathologists have hesitated to apply that term to them. But they resemble inflammation in being the result of irritation, and in being characterised by a diminished vitality of the affected part, as indicated by the readiness with which a slight injury converts the chronic process into an acute inflammation of the ordinary type. Microscopic examination of tissues or organs from different cases affected in this way shows every possible variation between the infiltration of the connective tissue with innumerable small round cells indistinguishable from the wandering leucocytes of acute inflammation, and the development of a tissue composed of dense rigid-looking fibres between which are found a few elongated cells. In fact, no sharp line can be drawn between acute interstitial inflammation and the chronic form with fibroid induration. In bone, chronic inflammation of this type is shown by thickening of the periosteum and formation of new bone beneath it, by increased density or sclerosis of the compact tissue, with narrowing or obliteration of the Haversian canals, or by condensation of the cancellous tissue. In arteries, the growth takes place chiefly from the outer layer of the inner coat, and the new tissue closely resembles the old in structure. This form of chronic inflammation is, as a rule, accompanied by more or less atrophy and degeneration of the higher tissues, their place being occupied by the overgrown connective-tissue, and for this reason it has been spoken of as a "fibroid substitution."

Another common effect of chronic inflammation is *ulceration*. Except in the slowness of its progress it differs in no respect from that occurring in acute inflammation. The tissues first become infiltrated with new cells, which accumulate and press on the original structures, finally destroying them and taking their place. Then in their turn the destroying cells perish, break down, and come away mixed with serous exudation as pus; and thus a gradual progressive destruction of tissue takes place. *Suppuration* often assumes a chronic form, as in the case of large abscesses proceeding from the thorax or abdomen, or from deeply-seated diseased joints or bones. The natural tendency of all abscesses, as soon as they are opened, is to fill up with granulation-tissue and to close; but when there is some source of irritation present, as decomposing matter, tension from imperfect drainage, or friction of one surface against another, the granulations break down into pus as quickly as they grow, and the process may thus be prolonged indefinitely, the only limit being the powers of endurance of the patient.

In chronic inflammations, although the connective-tissue may, as before described, undergo an increased development, the higher tissues always suffer degenerative changes—partly as a result of the pressure to which they are exposed from the new growth. Thus the tubules or acini of a chronically inflamed gland become obliterated, and muscular fibre in an inflamed muscle undergoes fatty degeneration. In this way the functional activity of organs suffering from chronic inflammation is more or less interfered with.

Thus we see that chronic inflammation, although differing widely from acute, does present some analogies to it. The development of increased connective-tissue is analogous to the adhesive or productive form of acute inflammation, and the formation of a cheesy centre, or a chronic abscess, differs chiefly in its chronicity from the process by which an acute abscess arises, while ulceration and some forms of suppuration are the same processes in both forms of inflammation, differing only in their rate of progress and duration.

No sharp line can be drawn between chronic and acute inflammations; and the term "**subacute**" is often used to signify processes in the border-land between the two.

Chronic inflammations, like the acute, may be *simple* or *infective*. Syphilis, tubercle and leprosy are examples of infective diseases of which chronic inflammatory processes form the essential pathological features.

Causes.—The causes of chronic inflammation are like those of the acute process, predisposing and determining. The **predisposing causes** are the same as those of acute inflammation; anything that tends to lower the vitality and interfere with healthy nutrition, either generally or locally, predisposes to one as much as to the other. Perhaps *passive congestion* forms the most common of all predisposing causes, and it is often difficult to draw a distinct line between the non-inflammatory changes, the induration and pigmentation resulting from congestion, and those produced by true chronic inflammation. Certain congenital or hereditary constitutional states form important predisposing causes, the most important of these being probably the condition commonly known as *scrofula* or the *scrofulous diathesis*. This is sometimes defined as a predisposition to tubercle in all its forms, but probably Virchow's definition of *scrofula* as an "abnormal vulnerability of the tissues" is the best. It is a condition of low vitality in which the tissues do not offer the normal resistance to external injurious influences of all kinds. Scrofulous subjects offer a feeble resistance to the invasion of all parasites, not only to the tubercle bacillus. (See Chapter on Tubercle and Scrofula.) Amongst the acquired constitutional conditions, *syphilis*, *rheumatism* and *gout* form frequent predisposing causes; so much so that in all chronic inflammations it is the duty of the Surgeon to bear in mind the possibility of one of these being present. The importance of the predisposing causes is undoubtedly relatively greater in the chronic than in the acute form of the inflammatory process, and this fact must be borne in mind in the treatment of the affection.

The **immediate causes** of chronic inflammation are of the same nature as those of the acute process, but they act with a less degree of intensity and more continuously. So long as the cause of the inflammation is present the process cannot subside. In chronic inflammation it often happens that the cause which starts the process is of a temporary character, the persistent effect being due to other causes which come into play at a later period. Thus in a common ulcer of the leg the history of the case is frequently as follows: The patient, possibly ill-nourished and feeble from want of proper food, suffers from varicose veins, which interfere with the return of blood from the skin of the leg, giving rise to a condition of passive congestion. As a result of this the skin of the leg is badly nourished and of low vitality, and incapable of withstanding the effects of even mild degrees of irritation. Sooner or later some slight injury, such as a scratch or blow, which would be harmless to healthy tissues, gives rise to inflammation of sufficient intensity to reach the stage of suppuration. The pus raises the cuticle, forming a small pustule which bursts, leaving a raw surface beneath. The discharge decomposes and irritates the surface, the clothes rub the ulcer, the muscles working beneath in walking move it about, the dilatation of the vessels and the exudation, added to the obstruction in front which originally gave rise to the congestion, produce tension; and all these causes combined, maintain the inflammatory process, the suppuration continues, and the sore slowly spreads by ulceration.

In such a case as this the predisposing cause, and the secondary causes, play by far the most important part, and the exciting cause that started the process may be so slight as almost to escape notice.

In many cases the nature or quantity of inflammatory products serves partly as a cause of the persistence of the process. Thus in the case of inflammation of the synovial or serous membranes, the tension caused by the effusion of fluid is sufficient to maintain the inflammatory process long after the original cause of mischief has been removed. In other cases, in which formation of new tissue is an important element in the process, the feebleness of the new growth, its imperfect development, or its insufficient vascularisation make it unable to withstand slight sources of irritation; and thus causes which would be harmless to healthy tissues perpetuate the inflammatory process in the new growth; or the new tissue may perish and, acting as a foreign body, excite inflammation in the tissues in contact with it.

In the chronic infective inflammations the essential cause is a specific virus. In tubercle it has been proved to be a specific organism—the tubercle bacillus. But granting this, it must not be forgotten that numerous accessory causes play a most important part in the development of tuberculous diseases. Hereditary tendency, bad hygienic surroundings, bad feeding, impaired health from other diseases as measles or whooping-cough, and local damage, may all act as predisposing causes, and not only is the development of the disease determined by these causes, but the course it follows is influenced in no less degree. Whether the chronic inflammatory process set up by the presence of the bacillus remains local or becomes general, whether it causes fibrous hyperplasia, caseation and softening with chronic suppuration, or whether its progress is rapid or slow, does not depend upon any variation in the essential cause, the bacillus, but in the accessory causes, such as the degree of rest given to the affected part, the general health and the hygienic surroundings.

In syphilis the nature of the poison is not known. In the early stages the virus itself seems to be the essential cause of the chronic inflammatory processes which form the pathological features of the disease, but after this stage has subsided there seems sometimes to be left behind an impairment of the constitution in which chronic inflammatory processes are readily induced, but in which there is no evidence of the presence of a virus communicable to another individual. Thus syphilis may be both a predisposing, and a determining cause of chronic inflammation.

LOCAL SIGNS.—The modifications of colour, size, sensation, function and temperature, described as attendant on acute inflammation, are present also in chronic inflammation; differing, however, in origin and in degree, and often in order and combination. The *colour* is not always changed, unless the part affected be very superficial; and the redness is rather of the dull than of the bright hue, not depending on the rapid transmission of an increased quantity of bright blood, but rather on a congestive condition. The affected tissue may become permanently discoloured by the escape of large numbers of red blood-corpuscles, which break up and are imperfectly absorbed, leaving the pigment behind. The *pain* is not often spontaneously acute, but partakes generally of the character of tenderness, being elicited only by pressure; sometimes, however, the pain is very severe. The increase of *temperature* is usually wanting, or very great. *Swelling* is an early and most important sign in chronic inflammation. It depends less on the enlargement of the vessels than on the

effusion which takes place, and the production of new tissue which often constitutes the distinctive characteristic of the disease. The *impairment of function* is constantly present as in acute inflammation, but to a very varying degree.

CONSTITUTIONAL SYMPTOMS.—These are less marked in chronic than in acute inflammation. The patient is in most cases, however, in impaired health: being, in many instances, affected with some constitutional taint which has had its influence in producing or maintaining the chronic character of the inflammation. In all cases in which there is chronic suppuration, and in most of the chronic infective inflammations, the pulse will be found to be above the normal standard, and slight febrile disturbance, often of a distinctly periodic character, is usually present. In these cases the temperature should be closely watched, and a rise towards evening especially noted as an important indication of a smouldering inflammatory process.

TREATMENT. CONSTITUTIONAL.—In chronic inflammation, the so-called antiphlogistic treatment is never required. Local nutrition is always deeply modified in chronic inflammation; and it can be restored to its normal condition only by improving the patient's general health, and at the same time producing an impression on the part itself by appropriate topical means. Hence, in the treatment of chronic inflammation, hygienic measures are of the first consequence. The treatment of this form of inflammation must likewise be varied according as it is uncomplicated, occurring in an otherwise healthy constitution; or as it assumes a congestive or passive character in a cachectic and feeble system; or as it is met with affecting a specific form in an unhealthy constitution.

In the majority of chronic, as of acute inflammations, it is necessary to give rest to the affected part, as in white swelling of a joint, or disease of the vertebrae, but as a rule confinement to bed should be avoided if possible. The patient should be in pure air: sea-air being especially useful in all tuberculous inflammations. The patient should be warmly clothed. The action of the bowels should be regulated, if necessary, by purgatives. Attention to the **diet** is of great importance; it should in all cases be light and unstimulating, sufficient in quantity, but not excessive.

Alcohol is very rarely required in the treatment of chronic inflammations; in fact, as its abuse is one of the most common predisposing causes of such affections, it is more commonly necessary to restrain the patient from its use than to encourage him in it. In tuberculous disease of any kind its use is only required when it encourages the appetite and aids digestion, and then it should be taken only with meals. The practice of giving such patients a glass of wine once or twice a day between meals to "keep up their strength" cannot be too strongly condemned. It does not really give strength, and the habit is apt to grow upon the patient during a long illness, and may become extremely troublesome. A little warm beef-tea or soup, or a cup of properly made tea will usually produce the desired effect more safely. In chronic suppuration with great exhaustion, as in the asthenic form of inflammatory fever, stimulants may be required. In gouty inflammations, and in most of those due to rheumatism, wine and beer should be avoided; distilled alcoholic drinks only being allowed, and those only in small quantities with meals. When, as is so often the case, the chronic inflammation is due to some definite constitutional affection, such as gout, rheumatism, or syphilis, the general treatment

is of even greater importance than the local, and must of course be directed to the special condition ; as, for example, saline purgatives and colchicum for gout, salicylate of soda for rheumatism, and mercury and iodide of potassium for syphilis.

Cod-liver oil, which may be regarded rather as an article of diet than a medicine, is often of the greatest value in strumous inflammations, especially in children and young people, when debilitated, emaciated or cachectic. It should always be given after meals, and when anemia is present, it may be advantageously conjoined with the preparations of iron, such as Steel-wine, the Syrup of the Iodide of Iron, or the Compound Syrup of the Phosphate of Iron (Parrish's chemical food), or the Syrup of Iron, Quinine and Strychnine (Easton's Syrup).

Mercury, given in small doses for a considerable length of time until the gums are slightly affected, is often of use, even in cases not definitely syphilitic in origin. It seems, in some cases, to hasten the absorption of the exudation and to aid in removing thickening, or sclerosis of the affected part. It should, however, on no account be given in cachectic or strumous constitutions, or for tuberculous disease of any kind. The perchloride in doses of one-sixteenth to one-twelfth of a grain may be given, conjoined with iron or cinchona if the patient's general health is somewhat depressed.

Iodide of potassium is an alterative and absorbent of the greatest value, especially in the chronic inflammations of fibrous or osseous tissues, or of the glands, occurring in strumous constitutions. In many cases it is of essential service after a mercurial course.

Various **natural sulphur waters**, such as those of Harrogate in England, Aix-la-Chapelle in Germany, Aix-les-Bains in Savoy, and the baths of the Pyrenees, especially Barezee, have always enjoyed a great reputation in the treatment of chronic inflammations, whether syphilitic, rheumatic or strumous. The treatment consists in hot bathing, combined with the internal administration of the waters. In syphilitic diseases mercury is given at the same time by inunction.

The **sulphides of calcium and potassium**, especially the former, given in small doses, have been recommended by Ringer as a substitute for the natural sulphur waters. He states that they are particularly useful in the chronic inflammations of scrofulous subjects, when there is a tendency to caseation of the inflammatory products, and slow elimination by softening and suppuration. In such conditions they hasten the process and shorten the course of the disease. Ringer recommends for a child a mixture of much the same strength as the Harrogate waters—viz. one grain of the sulphide of calcium dissolved in half a pint of water, and of this one teaspoonful may be taken hourly. In adults, in whom this mode of administering medicine is seldom possible, a pill containing one-quarter to one-third of a grain of the sulphide may be taken three times a day.

Other **mineral waters**, taken internally or used as baths, deservedly enjoy a great reputation in the treatment of many chronic inflammatory affections, the particular bath to be recommended depending upon the constitutional condition which forms the predisposing cause of the disease. Thus for anæmia and general debility iron waters, such as those of Tunbridge Wells in England, the Kniebis baths in the Black Forest, or Schwalbach ; for scrofulous affections, iodine waters, such as those of Kreuznach ; for gout,

alkaline waters, such as those of Vichy in France, or purgative waters, such as Carlsbad, or neutral waters, such as Bath, Baden-Baden, or Homburg: and for rheumatism, Buxton and Bath. In many chronic diseases of joints, hot salt baths, either of sea-water, artificial solution of salt or the natural brine springs of Droitwich, are very useful.

LOCAL TREATMENT OF CHRONIC INFLAMMATION.—In chronic inflammation, our local means of treatment are much more varied than in the acute form of the disease.

Local Blood-letting is scarcely ever useful in chronic inflammations.

Warmth and Moisture are not so serviceable in chronic as in acute inflammation, and care should be taken that they be not continued for so long a time as to make the parts sodden. An astringent or stimulant, such as liquor plumbi or spirits of wine, may often advantageously be added to the warm application.

In many chronic inflammations recovery is delayed by the passive congestion which so often accompanies the process. In these cases, although the part may possibly always contain an excess of blood, it circulates too slowly, and consequently there is really a diminished supply. Many of the most important means of treating chronic inflammation are intended to empty the congested vessels, and to cause an afflux of blood and a hastening of the circulation through the affected part, stimulating the tissues in the normal processes of absorption and repair. Thus **Cold**, not applied continuously as in acute inflammation, but for a short time twice or thrice a day, by douching with cold water, is often of great use. It first tends to cause a contraction of the vessels, which, perhaps, by calling them actively into play, exercises them as it were, and tends to restore their healthy tone; and this is followed by dilatation, with an increased flow of blood through the affected part, thus improving the nutrition of the tissues and hastening their repair. A somewhat similar effect may be produced by the use of **Electricity**, in the form of the continuous current: but perhaps the most useful of these modes of treatment is **Rubbing, or Massage**. Rubbing acts in several ways. First, it mechanically empties a congested part of blood, causing a fresh flow to it, and thus promotes healthy nutrition; secondly, the mechanical stimulus causes a contraction of the muscular coats of the vessels followed by a relaxation, thus exercising them and aiding in restoring their normal tone; thirdly, if properly applied, it empties the lymph-spaces, and thus aids in relieving the part of serous or inflammatory exudation; fourthly, it stimulates the contraction of muscles which have been thrown out of work (as in the case of an inflamed joint), and thus maintains their nutrition; and, lastly, it helps to break down adhesions amongst contiguous structures.

Rubbing must be done with sufficient force to produce the desired effect, but not so violently as to injure the skin. A skilful rubber can do this without greasing the hand, but usually it is better to use a little oil. If it be desired to produce a greater afflux of blood, some stimulating liniment may be used, but this is not usually of any great advantage. The time for which the rubbing should be kept up varies with the case from a quarter to half an hour or more. The more chronic the case, the longer will the rubbing be required. Rubbing is chiefly applicable to chronic inflammations of joints, synovial membranes and muscles, and it is undoubtedly one of the most efficient means of treatment that we possess. A large amount of training and

experience is required to produce a perfect rubber, one, for instance, who can pick out the individual muscles and stimulate them to contraction; but, fortunately, such high art is seldom required. In the majority of cases, a few lessons will enable anyone gifted with ordinary intelligence to rub a chronically inflamed part with sufficient skill to produce some good effect. The points to be attended to are to rub always in the direction of the circulation, not up and down as is commonly done; to use the right amount of force, and yet not to make the skin sore, and to rub for a sufficient length of time. That a trained *masseur* is in every way superior to an unskilled amateur need not be said, and wherever it is possible to obtain the services of a professional rubber it is wise to do so, but in private practice in the country, and amongst the poor, such a luxury is not to be had, and much good may be done even by an amateur.

Counter-Irritants are local applications which give rise to irritation of the skin of varying intensity according to their nature, the mildest forms, as a camphor liniment, causing merely a passing dilatation of the cutaneous vessels, and the most severe, as the actual cautery, producing destruction of the skin and even of part of the subcutaneous tissue. The value of counter-irritants is recognised by all practical Surgeons, and they are undoubtedly amongst the most effective local means that we possess for combating chronic inflammation: yet their mode of action is difficult to explain. The old theory that by exciting a local inflammation in the skin it was possible to draw the disease away from the deeper and more important parts is no longer tenable; the theory that by stimulation of the sensory nerves of the skin a dilatation of the superficial vessels is produced, accompanied by a corresponding contraction in the deeper parts, cannot be supported by scientific evidence; in fact, as Billroth has pointed out, it is probable that in many cases, especially in extremely sluggish chronic inflammations, the good produced is probably rather by an increased afflux of blood to the affected part than by a diminution of the blood supply. Most counter-irritants are applied solely with the intention of causing a certain degree of hyperæmia or of inflammation in the part of the skin on which they are placed, while others exert, or are supposed to exert, at the same time a constitutional effect, being absorbed into the system from the cutaneous surface. Counter-irritants are classed according to the degree of local irritation they give rise to.

Rubefacients are those that cause merely a dilatation of the vessels of the part to which they are applied, such as camphor liniment, mustard poultices, Rigollot's mustard leaves, capsicum plasters, &c. In surgery, they are chiefly used in rheumatic inflammations of muscles or nerves.

Vesicants are those applications which cause a degree of inflammation sufficient to give rise to abundant exudation, which raises the corneous layer of the cuticle from the Malpighian layer beneath, thus forming a bleb or blister. Vesicants are extensively used in surgery to promote absorption of the products of chronic inflammation, and in some cases to check the process, as in the application of blisters in chronic synovitis or periostitis, or to the perineum in chronic prostatitis.

The preparations of cantharides are the chief blistering agents employed; of these the two most common are the *Emplastrum Cantharidis*, or common fly-blisters, and the *Liquor Epispasticus*. The former is applied to surfaces free

from hair, the latter to the scalp or perineum. In applying a blister, or the *opoplasticus*, it is essential that the part should be as free from grease as possible, and for this purpose it must be washed with soap and hot water, and afterwards, if it can be conveniently done, sponged over with a very dilute solution of ammonia, before the blister is put on. The blister should rise in from eight to twelve hours. When the bleb is fully formed, if it is not intended to prolong the action, it should be carefully pricked with a needle, but the cuticle should not be removed. It should then be covered with cotton-wool and a bandage, or a little simple ointment on a piece of linen. If it be desired to prolong the counter-irritation, the cuticle may be removed, and the raw surface dressed with savin ointment, by which means it may be kept open as long as is wished.

A blister does not, as a rule, leave a scar; but it may do so, and it is well therefore not to apply it to the face or hands if this can be avoided. The extent of surface to which it is applied must not exceed a few square inches, for there is some danger of the absorption of the cantharidine, and of consequent congestion of the kidneys, hæmaturia, and strangury. This will of course happen more readily if there be a raw surface beneath the plaster. Blisters must always be used with great caution in very old or feeble subjects, and in those suffering from Bright's disease, or any other serious visceral affection, as in such cases they occasionally cause sloughing.

Suppurants or Pyogenic counter-irritants are those agents which are of sufficient intensity to give rise to inflammation reaching the stage of sup-

Fig. 87. Introduction of a Seton.

uration. The most common of these are croton oil, issues, setons, and the actual cantery. An *issue* was a suppurating sore, made with a caustic and kept open by savin ointment, or a pea put in the middle of it and retained in position by plaster. A *seton* consisted of a few threads of silk passed under a fold of skin, in the way shown in Fig. 87. The suppurating track was often kept open for many months. Both these modes of treatment are now abandoned.

The **Actual Cantery** is very successful in chronic inflammation of joints before destruction of the cartilages has set in, and it is especially useful when there is great pain with nocturnal startings. The relief given by it is often immediate and permanent. In the application of the cantery it is the object of the Surgeon to destroy the cuticle and the tips of the papillæ, but to leave the deeper structures of the skin uninjured, so that there shall be no interruption of the scar when the sore has healed.

For this purpose the cauterising iron should be of a dull red heat, and must

be quickly drawn in lines crossing one another over the part. Paquelin's Thermo-Cautery is on the whole the most manageable and the cleanest form that can be used. The barbarous application known as a *moxa*, which consisted of cotton or pith soaked in saltpetre and allowed to burn upon the skin, is now no longer used in this country.

Two counter-irritants in addition to their local action produce constitutional effects when absorbed from the surface to which they are applied—viz. Iodine and Mercury.

Iodine is most commonly applied in the form of tincture; it should be painted over the inflamed part twice a day till the skin becomes a little sore. This may be continued for weeks or months according to circumstances. It is no doubt a useful means of promoting the absorption of chronic inflammatory products, but the powers popularly ascribed to it are certainly far greater than it really possesses. The liniment is less frequently used, being a much stronger preparation, one application of which will often cause vesication. The iodine or iodide of lead ointment may be applied in cases in which a somewhat stronger action than that of the tincture is desired, but they are not cleanly applications, and are not usually to be recommended.

Mercury is applied locally in many forms to promote the absorption of the products of chronic inflammation and in the treatment of the process. One of the most common modes of applying it to chronically inflamed joints is in the form of "Scott's dressing." This consists in spreading a thin layer of the compound mercurial ointment on a piece of lint of sufficient size to surround the joint. Over this strapping is evenly applied so as to exert a uniform pressure. In other cases the mercurial liniment or simple mercurial ointment may be of use. John Marshall introduced an elegant preparation composed of the precipitated mercuric oxide dissolved in oleic acid. There is thus formed a definite oleate of mercury which is soluble in an excess of oleic acid. A solution made in this way containing five per cent. of the oxide is a clear liquid; when the oxide is increased to twenty per cent. it forms a solid unctuous substance, melting readily at the temperature of the body. As the oleate of mercury is slightly irritating to the skin, one grain of morphia may be added to each drachm. Marshall states that his experience of the use of this preparation in all forms of chronic inflammation has been very favourable. It is cleaner, more diffusible, more readily absorbed, and more efficacious than any other mercurial application. The very fact, however, that it is so readily absorbed forbids our using it in scrofulous subjects, who always stand mercury badly. Ten to thirty drops of the oleate, melted if necessary by a very gentle heat, and applied with a camel's-hair pencil, are quite sufficient for one application.

Astringents applied directly to the inflamed parts are of the greatest service in those forms of congestive or purgative inflammation in which the circulation is sluggish and the capillaries loaded; they afford relief in these cases by inducing contraction of the vessels. In order to ensure their proper action, they must be employed of sufficient strength; for if too weak they irritate, and increase rather than relieve the congested condition. The nitrate of silver is the astringent that is commonly preferred; this may be applied either solid or in a solution containing from ten grains to one drachm of the salt in one ounce of distilled water, and will produce a very marked beneficial influence in congestive inflammation of mucous, and occasionally of cutaneous, surfaces.

Pressure by means of well-applied bandages, elastic webbing, or strapping, is of essential service in supporting the feeble vessels in congestive inflammations. In many cases pressure may be advantageously conjoined with absorbents and rubefacients, as mercurial and camphor liniments, or the plaster of mercury and ammoniacum. This treatment, by removing congestion, and promoting the absorption of inflammatory effusion, is especially useful in chronic forms of inflammation accompanied by thickening of parts, as in the joints and testes.

CATARRHAL INFLAMMATION.

Catarrh or catarrhal inflammation is a form of the process of inflammation affecting mucous membranes and other epithelium-covered surfaces. All these are liable like other structures to traumatic inflammations of the ordinary type, in which, as a consequence of the action of some irritant, the vessels dilate, the circulation is retarded, the white corpuscles migrate and the liquor sanguinis stases, and the functional activity of the original cells is suspended or permanently abolished. The peculiarity of the catarrhal form, however, consists in the fact that, although the vessels are dilated and exudation of blood-plasma and even the abundant escape of white corpuscles is taking place, yet the epithelium continues to exist and perform its function, and in most cases its cells multiply with unnatural rapidity. Catarrh may arise from the direct application of an irritant to the surface of the mucous membrane, as in the case of decomposing urine irritating the bladder or of gonorrhoeal pus acting on the urethra. At first sight it seems difficult to explain why in these cases the vessels of the corium and the submucous tissue should show signs of damage, by their giving exit to an abundant exudation and by the white corpuscles passing through their walls, while the epithelium is comparatively unimpaired, showing signs rather of stimulation than of impaired function. It must not be forgotten, however, that surface-epithelium is a structure which possesses in a high degree the power of resisting external injurious influences; and it is quite conceivable, therefore, that a cause which exerts no more than a stimulating action on the epithelium may, if it penetrate to the parts beneath, give rise to the phenomena of inflammation.

In other cases the cause of catarrh is not so clear, as when a patient is attacked by bronchitis, catarrhal nephritis, or cystitis, as the result of "catching cold." In these cases it is probable that the contraction of the cutaneous vessels causes hyperemia of the internal organs, but hyperemia alone is not sufficient to cause catarrh; probably the inflammation is due in part, at least in the case of the lung and kidney, to increased work thrown upon these organs in the elimination of those products of tissue-change which should be given off by the skin. Our knowledge is not, however, as yet sufficient to explain rationally the origin of all catarrhal inflammation.

The changes in the affected membrane depend on the degree of the process. In the mildest form there is some swelling due to exudation of serum. This partly distends the loose submucous tissue, and drains off by the lymphatics, and partly flows away from the surface of the membrane. At the same time the cells of the epithelium multiply more quickly than natural, and many are loosened and come away with the discharge. If this loss of epithelium is very considerable the process is described as *desquamative catarrh*. In all

tion of mucus during catarrh.
 A marked clinical feature of the
 is **purulent catarrh**, the vessels
 are widely dilated and the flow through
 is copious, and the white corpuscles
 are thus leave the vessels, wander
 on the surface, forming with the liquid exuda-
 tion in such a case, if examined micro-
 scopically, numerous amoeboid cells, presenting the
 appearance of pus-cells; ordinary pus-cells, round and
 containing epithelium-cells, some fully developed
 and attached to the affected membrane, some
 partially developed, and others containing a
 nucleus. A microscopic examination of a section
 of the abundant discharge of pus, there-
 fore covered by epithelium. The wandering
 cells between the vessels and immediately beneath the
 epithelium-cells will be found to contain within
 them pus-corpuscles. These were supposed by
 some to be the origin of purulent catarrh was formed by endogenous
 cells. Later observations, however, have
 shown that mother-cells are in reality dead or dying
 and penetrated by wandering leucocytes. Wan-
 dering between the individual epithelium-
 cells, as, for example, in gonorrhoea,
 and the process are found in the epithelium and

in inflammation there need be no ulceration,
 and readily one process may be converted into
 another. Epithelium-cells to each other, and to the corium,
 in severe forms of catarrh; should the loosely
 attached cells be mechanically removed by violence from without, or
 by necrosis beneath, a small ulcer will be the result.
 Catarrh, like other forms of inflammation, may
 be of the simple form is very frequently associated with
 ulceration. It may also be *simple*, as in bronchitis,
 conjunctivitis, or gonorrhoea. The thick mucus
 on the surface of a mucous membrane during
 catarrh acts as a nidus for the growth of microscopic
 organisms; these set up give rise to products
 which penetrate and cause it to spread almost indefinitely.
 On the affected surface, with slight swelling and an
 increase in the secretion, the fluid changes from a pure serous to a thick muco-purulent fluid,
 the features of a catarrhal inflammation. The heat
 is not a marked symptom except in the more
 severe forms, as in ophthalmia. The constitutional symptoms vary
 with the extent of the process and the part affected. As a rule, only the
 local symptoms give rise to any elevation of temperature. The

absence of fever may possibly be accounted for by the fact that the exudation drains away from the surface and but little finds its way back into the blood-stream.

Parts which have suffered from chronic catarrh, or from repeated attacks of the acute form, usually become more or less pigmented, and the sub-mucous tissue is thickened and indurated. These signs are well seen in the mucous membrane of the bladder in cases of old stricture or stone.

The **treatment** of catarrhal inflammation presents little that requires special notice. In the more acute forms warmth and moisture, and above all removal of the discharge and prevention of its decomposition, form the most important means of treatment. Belladonna is often of use locally in diminishing pain and promoting contraction of the small arteries. In chronic catarrh, removal of the secretion and cleanliness with the use of astringents, and antiseptics, such as nitrate of silver, acetate of lead, sulphate of copper or tannin, boric acid, iodoform, &c., form the chief treatment. Any constitutional condition such as scrofula or gout must be searched for and treated.

CHAPTER V.

SUPPURATION AND ABSCESS.

SUPPURATION, or the formation of pus, has already been described in Chapter on Inflammation. It was there pointed out that the process consists of a continuance and exaggeration of one of the features of inflammation—migration of the white corpuscles. The process of suppuration may be diffuse or circumscribed. When diffuse, the leucocytes and the liquid exudation distend the lymph spaces of the affected part without the formation at first of any distinct cavity containing pus, as in phlegmonous erysipelas or diffuse cellulitis. This, as will be seen afterwards, is due to the rapid diffusion of the irritant causing the suppuration through the lymph spaces. Circumscribed suppuration may occur in two forms, first from a surface, as a granulating wound, secondly subcutaneously, when the pus accumulates in a newly-formed cavity or abscess.

In the formation of an acute abscess the wandering cells accumulate on the vessels, and possibly multiply by division in their new situation, but this is extremely doubtful; as the accumulation increases, the original tissue already damaged by the irritant which is causing the inflammation, becomes pressed upon and absorbed, and the new cells occupy their place; finally, the central cells of the group degenerate from want of nutrition, or perish from the direct action of the irritant, their intercellular substance softens, and the liquid exudation from the surrounding part soaks in amongst them, and we get a creamy fluid, or pus.

If, as sometimes happens, we have the opportunity of examining microscopically such a small collection of pus in the subcutaneous tissue, the following appearances are observed, proceeding from the circumference to the centre of the affected area. The first sign of deviation from health is that some scattered leucocytes are seen in the spaces between the fibres of the connective tissue, and often evidently in the neighbourhood of a small vessel; as the centre is approached, the number of these increases, gradually obscuring the connective tissue and its corpuscles, till at last nothing is to be seen but closely-packed small round cells, between which the amount of intercellular substance is so small to be recognised; in the centre of this group of cells may be a cavity from which the pus has escaped in preparing the section. Amongst the closely-packed cells surrounding the collection of pus, micro-organisms can almost invariably be demonstrated by proper staining and preparation of the specimen. The connective tissue, when it is last recognisable before being concealed by the infiltrating leucocytes, is seen to have its fibres swollen and vitreous in appearance, while its corpuscles are unchanged or degenerating. These evidently are taking no part in the formation of the new cells which are crowding amongst the fibres. If any blood-vessels are recognisable, it will be seen that, near the point at which everything is concealed by the leucocytes, they are filled with closely packed blood-corpuscles, indicating the presence

clot. It is in this way that they are closed before, in common with the other tissues, they soften and break down in the presence of the invading leucocytes, and thus hæmorrhage is prevented. In this area also, although it cannot be seen with the microscope, the plasma which has exuded from the vessels is coagulated, and with the migrated cells forms a firm substance, the so-called inflammatory lymph, which fills and plugs the spaces of the connective tissue, and thus forms a barrier round the collection of pus, and prevents its diffusing itself amongst the tissues around. It is not possible in a section made from a preparation removed from the body to observe the state of the vessels beyond the area of stasis or thrombosis; but if we could observe them in the living body we should see, in a spreading abscess, all the conditions already described

FIG. 1. A Microscopic Abscess in the Skin. *e*, Epithelium; *h*, a Hair; *s*, *c*, Small Vessels surrounded by plasma by migrating leucocytes; *p*, the collection of pus; *s*, Sweat-gland; *h*, a small Artery; *h*, *h*. The tissues round the collection of pus are dotted with leucocytes becoming more closely dotted as the centre of suppuration is approached.

under inflammation: viz. from the centre towards the circumference, stasis, oscillation, dilated vessels with retarded flow, adhesion of the corpuscles, and migration, and lastly, simple hyperemia, dilated vessels with increased capacity of flow. Such a collection of pus as is above described is a microscopic abscess: an acute abscess, holding half a pint, differs from it only in size. The extension of the abscess takes place by progressive destruction of the tissues by the same process; and the pus is formed by successive zones of the new cells degenerating, becoming separated from each other by fluid, and falling into the cavity. In this way the collection of pus advances towards a free surface and finally discharges itself. This "pointing of the abscess," as it is termed, advances most rapidly in the direction of least resistance, probably because the migration of the leucocytes and dilatation of the vessels occur more readily on that side. The whole process is identical with ulceration,

but instead of the discharge being given off superficially as in an ordinary ulcer, it accumulates in the abscess-cavity; an abscess is in fact a cavity enclosed by an ulcer. The zone of tissue in which the process of spreading is taking place was in former times spoken of as the "pyogenic membrane"; but it is evident that there is nothing to which the term "membrane" could properly be applied; the "pyogenic zone" would be a more correct term if any such is necessary. In this pyogenic zone the vessels are dilated and the tissues softened, so that in opening an abscess blood may flow freely from the engorged vessels round the cavity; but it must not be concluded from this that the abscess-cavity is surrounded by a zone of tissue in which new vessels have been formed. During the spreading stage of an abscess, it is destruction of vessels, not new formation, that is taking place; the new formation occurs only during repair, after the pus has been let out.

The method in which pus is formed on mucous surfaces in purulent catarrh has been described with that process.

That all the pus-cells in acute suppuration are derived from the white corpuscles may now be regarded as an established fact. The proof of this is derived partly from the direct observation of the formation of pus, as it has already been described, and partly from the experiments of Cohnheim, von Recklinghausen, and others. These observers injected aniline blue or cinnabar into the blood-stream of the animal to be experimented on. It has before been shown that when solid matter in a state of extremely fine division is injected into the blood-stream, the white corpuscles pick up the particles in the same way as an amoeba takes its food; and the dark-coloured particles of aniline blue or cinnabar are easily recognised in their substance. A frog having been prepared by the injection of the colouring matter, inflammation of sufficient intensity to cause suppuration was excited; and it was found that, whether it was in a vascular part or in a non-vascular, as the cornea, the pus-cells contained particles of the substance which had been injected.

Lastly, there is the negative observation, that in acute inflammations the original cells of the affected part undergo no change so long as they can be observed; that is to say, before they are concealed by the crowds of migrating leucocytes.

In the case of chronic suppuration from the surface of a healing ulcer the purulent fluid must contain many of the superficial granulation-cells which have perished and been cast off. These, as we shall see in the Chapter on Repair, are probably derived from the original cells of the affected part, and are practically indistinguishable from pus-cells derived from migrated corpuscles. This may, however, be regarded rather as an accident than as part of true suppuration.

Characters of Pus.—The pus from an acute abscess is an opaque, creamy fluid, thick, smooth, and slightly viscid, of a yellowish-white colour, with in some cases a greenish tinge; it has a faint odour and an alkaline reaction. Its specific gravity is from 1030 to 1040. Its chemical constitution varies slightly in different cases. It contains from 85 to 90 per cent. of water. Dried pus contains on an average about 67 per cent. of proteins, chiefly identical with those found in white blood corpuscles, 14 per cent. of fatty matter, half of which is lecithin; about 7 per cent. of cholesterin, and 10 of active, and 2 per cent. of salts. The chief inorganic constituents are chloride, calcium, magnesium, and ferric phosphates; calcium phos-

phos is said to be more abundant in pus coming from bone, but this is doubtful—there is merely a trace of potassium. The serum separated from the corpuscles contains about 90 per cent. of water. Of the solid constituents over 6 per cent. are proteids; not more than 15 per cent. lecithin and other fats; and about 75 per cent. salts, chiefly sodium chloride. It will be seen, therefore, that the lecithin and other fatty matters are chiefly contained in the corpuscles. Pus contains no fibrinogen, but fibrin-ferment has been shown to be present in it. The absence of fibrinogen in pus is most easily explained by supposing that the exudation from the vessels first coagulates in the zone in which the liquid pus has not yet formed, and then softens and breaks down. In addition to the above constituents, peptones and albumoses are found, formed under the influence of the micro-organisms which are constantly present in all acute suppurations. Leucin, tyrosin, and various other important substances are also often found in pus. Pus also frequently contains the specific virus of the disease with which its formation is connected, as in small-pox, glanders, tetanus, soft chancres, gonorrhœa, &c. The organisms specially connected with suppuration will be described later on. Many of the chemical substances found in pus have intense fever-producing (pyrogenic) powers if injected into the blood-stream.

Pus presenting the above characters is termed healthy or laudable pus (*pus bonum et laudabile* of the old writers), but various other terms are employed to indicate different appearances: thus, when tinged with blood it is called *sinuous*; when thin and watery, *ichorous*; when containing cheesy-looking flakes, *curdy*; and when diluted with mucus, *mucopus*. Besides these, pus presents other varieties; thus, for instance, when it is formed in the brain it is of a greenish tint, and when in the neighbourhood of the alimentary canal it has a peculiar, fetid odour.

Pus is a liquid which readily putrefies when exposed to the air or mixed with water at the temperature of the body, or even if septic organisms be introduced subcutaneously, as by an aspirator-needle or trochar. Thus we occasionally see that a collection of pus which, when tapped for the first time, is free from putrefaction, becomes offensive in a few days unless proper antiseptic precautions are taken during the operation. In some rare cases the pus, soaking a dressing, assumes a distinctly blue colour from the development in it of a special form of organism, the *bacillus pyocyaneus*. Blue pus is never found in a freshly opened abscess.

Microscopic Characters.—Pus consists of corpuscles floating in a clear fluid, the "*liquor puris*." In pus drawn from an acute abscess or from the surface of a healthy granulating sore, living cells, presenting amoeboid movements if examined on a warm plate, and dead cells which have undergone degenerative changes, are met with, the latter being the true pus-cells, and by far the more abundant. The living cells are mono-nucleated and poly-nucleated leucocytes, and have already been described (*see* Migration of the leucocytes). The typical "*pus-cells*" are the dead or degenerating leucocytes. They are rounded in form and slightly irregular in outline, and measure about 10–15 μ in diameter, and their protoplasm is coarsely granular, so that the nucleus is completely concealed. By treating with dilute acetic acid the granules are to a great extent dissolved, the protoplasm becomes swollen, and the nucleus comes clearly into view. It is then seen to be composed of three, sometimes of four or two parts, usually devoid of nucleoli

(Fig. 89). This breaking up of the nucleus has usually been regarded as a part of the degeneration of the migrated leucocyte, as the nucleus does not present the peculiar appearances observed in multiplication of cells by division of the nucleus (*karyokinesis*). On the other hand, as before stated (p. 163), Metchnikoff asserts that the greater number of migrating leucocytes are polynuclear at the time of migration, when they are manifesting their amoeboid and phagocytic properties with the greatest activity. In addition to the granules, which can be cleared up by acetic acid, pus-cells contain a varying

Fig. 89. Pus cells from Acute Abscess, before and after treatment with acetic acid.

number of fat granules formed by fatty degeneration of the protoplasm. These may be so abundant as to conceal the nucleus after the addition of acetic acid. They are dissolved by ether and liquor potassæ. The older the pus the more complete is the fatty degeneration and the less the nucleus can be stained by logwood or aniline dyes. Finally, in old collections of pus the cells may break up completely

and the granules float free in the liquor puris. It is usually possible to demonstrate the presence of micro-organisms not only free in the liquor puris but in the protoplasm of the pus-cells; the more degenerate the cells the more difficult it is to do this. In the pus of acute abscesses granular *débris* derived from the broken-down tissues are usually present, and fibres of yellow elastic tissue, which are the most resisting of all, may sometimes be recognised.

Diagnosis of pus from other fluids must be made by the microscope. The presence of the characteristic pus-cell above described is certain proof that the fluid in question is composed in part at least of pus.

The relation of Micro-organisms to Suppuration.—It was first shown by Alexander Ogston, of Aberdeen, that the pus of all acute abscesses contains micro-organisms, and his observations have been extended by Rosenbach, Koch, and a large number of other observers, until it may be said now to be an accepted fact that all acute suppurations with which the Surgeon has to deal, whether superficial or deep, are associated with the presence of micro-organisms. The investigation of this subject has been carried out in three ways:—First, by the direct observation of properly stained and prepared specimens of pus; secondly, by the cultivation of the organisms in solid or in liquid media; and lastly, by the inoculation of animals, and, in some cases, of the human subject, with the organisms derived from pus.

The important subject of the relation of micro-organisms to suppuration is best considered under six headings. First, a description of the organisms most commonly met with in acute suppuration; secondly, the proof of the pyogenic properties of the organisms; thirdly, the mode of action of the organisms and the part they take in causing suppuration; fourthly, can suppuration occur without the intervention of micro-organisms? fifthly, can simple septic bacteria give rise to suppuration? and lastly, what accessory causes commonly aid in the causation of suppuration?

The examination of pus for microscopic organisms has been rendered so simple by the methods introduced by Weigert, and perfected by Koch, and the

interest attaching to the subject is so great, that it may be well here briefly to describe the process. The reagents required are, a solution of methyl-violet (one of the aniline dyes), of the strength of half a grain to one ounce of distilled water, carefully filtered, and some pure Canada balsam, which has been heated to drive off its volatile oil. The method of observation is as follows: Spread the pus on a glass cover-slip in the thinnest possible layer, and dry it carefully over a spirit-lamp, taking care not to overheat it: dip a clean glass rod in the methyl-violet solution, and spread a thin film of the dye over the dried layer of pus: after from thirty to sixty seconds, wash the dye off carefully with a gentle stream of distilled water. A darkly-stained film should remain behind, which must be again dried over the spirit-lamp; then while the cover-slip is still warm, put on it a drop of the Canada balsam, rendered fluid by heat, and place it quickly on a glass slide which is also slightly warmed; squeeze it gently down, and when cold it is ready for examination. The micrococci are distinguished from other granules by their definite round form and uniform size, and by their arrangement in groups or chains. They, moreover, take the dye readily, while fatty and albuminoid granules remain uncoloured. Blood or urine may be examined by the same process.

There are, of course, many other methods of staining and preparing organisms, but the above will be found practically efficient for the ordinary pyogenic organisms.

The Chief Micro-organisms connected with Acute Suppuration.—In about 70 per cent. of all acute subcutaneous suppurations the organism present is a micrococcus (see p. 178) belonging to the group *Staphylococcus*, so named from the separate cells being heaped together in irregular masses resembling a bunch of grapes (Fig. 90). *Staphylococci* grow well at ordinary temperatures on

Fig. 90. — Pus from Acute Abscess, containing the *Staphylococcus pyogenes*.

nutrient gelatine, agar-agar and potatoes. When grown on gelatine they gradually liquefy it, and at the same time a slightly sour smell is given off. They generate no gas in their growth, and can either derive the oxygen from the air or from the tissues or fluids in which they may be growing in the body, that is to say, they can be aerobic or anaerobic, according to circumstances. Two chief varieties are commonly met with, *Staphylococcus pyogenes aureus* and *albus*. They are only distinguished by their growth on the various culturing media, the aureus forming colonies of a golden-yellow colour, and the albus forming opaque white patches. The two forms are frequently found together in the same abscess, and are probably mere varieties of the same species. In rare cases another variety forming lemon-coloured colonies has been met with, and has received the name of *Staphylococcus pyogenes citreus*. The staphylococci give rise to localised suppurations, and show no tendency to diffuse themselves widely by the lymph spaces. On the other hand, they frequently penetrate the small vessels of the part in which they are growing, and

mucous membranes there is an exaggerated formation of mucus during *catarrh*, and this increased secretion forms the most marked clinical feature of the milder form of the affection.

In more intense catarrhal inflammations, or **purulent catarrh**, the vessels of the corium of the mucous membrane are widely dilated and the flow through them is retarded; liquid exudation is more copious, and the white corpuscles migrate abundantly. The leucocytes, which thus leave the vessels, wander amongst and through the epithelium-cells, the natural cohesion of which is somewhat loosened, and escape on the surface, forming with the liquid exudation a purulent discharge. The discharge in such a case, if examined microscopically, will be found to contain—numerous amoeboid cells, presenting the usual appearance of white blood-corpuscles; ordinary pus-cells, round and granular, with the tripartite nucleus; and epithelium-cells, some fully developed and corresponding in form to that natural to the affected membrane, some of rounded form, young and imperfectly developed, and others containing a large transparent globule of mucus. A microscopic examination of a section of the membrane shows that, in spite of the abundant discharge of pus, there is no raw surface; everywhere it is covered by epithelium. The wandering cells can be seen in the corium round the vessels and immediately beneath the epithelium. Some of the epithelium-cells will be found to contain within them several bodies identical with pus-corpuscles. These were supposed by Rindfleisch to show that the pus in purulent catarrh was formed by endogenous cell formation from the epithelium-cells. Later observations, however, have tended to prove that these apparent mother-cells are in reality dead or dying epithelium-cells, which have been penetrated by wandering leucocytes. Wandering leucocytes are also found penetrating between the individual epithelium-cells. In some forms of catarrhal inflammation, as, for example, in gonorrhœa, the micro-organisms which cause the process are found in the epithelium and pus-cells.

Although in purulent catarrhal inflammation there need be no ulceration, the above description shows how readily one process may be converted into the other. The adhesion of the epithelium-cells to each other, and to the corium, is always loosened in the more severe forms of catarrh; should the loosely adherent epithelial layer be accidentally removed by violence from without, or separated by exaggerated cell-migration beneath, a small ulcer will be the result.

Varieties of Catarrh.—Catarrh, like other forms of inflammation, may be *acute* or *chronic*. The chronic form is very frequently associated with passive hyperæmia of the part affected. It may also be *simple*, as in bronchitis, or *infective*, as in purulent ophthalmia or gonorrhœa. The thick muco-purulent secretion that forms on the surface of a mucous membrane during a simple catarrh frequently serves as a nidus for the growth of microscopic organisms, and the fermentative changes these set up give rise to products which may prolong the irritation and cause it to spread almost indefinitely.

Symptoms.—Redness of the affected surface, with slight swelling and an abundant secretion varying from a pure serous to a thick muco-purulent fluid, form the most marked clinical features of a catarrhal inflammation. The heat is usually moderate, and pain is not a marked symptom except in the more acute forms, as in purulent ophthalmia. The constitutional symptoms vary with the acuteness of the process and the part affected. As a rule, only the most acute forms of catarrh give rise to any elevation of temperature. The

absence of fever may possibly be accounted for by the fact that the exudation drains away from the surface and but little finds its way back into the blood-stream.

Parts which have suffered from chronic catarrh, or from repeated attacks of the acute form, usually become more or less pigmented, and the sub-mucous tissue is thickened and indurated. These signs are well seen in the mucous membrane of the bladder in cases of old stricture or stone.

The **treatment** of catarrhal inflammation presents little that requires special notice. In the more acute forms warmth and moisture, and above all removal of the discharge and prevention of its decomposition, form the most important means of treatment. Belladonna is often of use locally in diminishing pain and promoting contraction of the small arteries. In chronic catarrh, removal of the secretion and cleanliness with the use of astringents, and antiseptics, such as nitrate of silver, acetate of lead, sulphate of copper or tannin, boric acid, iodoform, &c., form the chief treatment. Any constitutional condition such as scrofula or gout must be searched for and treated.

CHAPTER V.

SUPPURATION AND ABSCESS.

SUPPURATION, or the formation of pus, has already been described in Chapter on Inflammation. It was there pointed out that the process consisted of a continuance and exaggeration of one of the features of inflammation—migration of the white corpuscles. The process of suppuration may be diffuse or circumscribed. When diffuse, the leucocytes and the liquid exudation distend the lymph spaces of the affected part without the formation at first of any distinct cavity containing pus, as in phlegmonous erysipelas or diffuse cellulitis. This, as will be seen afterwards, is due to the rapid diffusion of the irritant causing the suppuration through the lymph spaces. Circumscribed suppuration may occur in two forms, first from a surface, as a granulating wound, secondly subcutaneously, when the pus accumulates in a newly-formed cavity or abscess.

In the formation of an acute abscess the wandering cells accumulate outside the vessels, and possibly multiply by division in their new situation, but this is extremely doubtful; as the accumulation increases, the original tissue already damaged by the irritant which is causing the inflammation, becomes pressed upon and absorbed, and the new cells occupy their place; finally, the central cells of the group degenerate from want of nutrition, or perish from the direct action of the irritant, their intercellular substance softens, and the liquid exudation from the surrounding part soaks in amongst them, and thus we get a creamy fluid, or pus.

If, as sometimes happens, we have the opportunity of examining microscopically such a small collection of pus in the subcutaneous tissue, the following appearances are observed, proceeding from the circumference to the centre of the affected area. The first sign of deviation from health is that some scattered leucocytes are seen in the spaces between the fibres of the connective tissue and often evidently in the neighbourhood of a small vessel; as the centre is approached, the number of these increases, gradually obscuring the connective tissue and its corpuscles, till at last nothing is to be seen but closely-packed small round cells, between which the amount of intercellular substance is so small to be recognised; in the centre of this group of cells may be a cavity from which the pus has escaped in preparing the section. Amongst the closely-packed cells surrounding the collection of pus, micro-organisms can almost invariably be demonstrated by proper staining and preparation of the specimen. The connective tissue, when it is last recognisable before being concealed by the infiltrating leucocytes, is seen to have its fibres swollen and vitreous appearance, while its corpuscles are unchanged or degenerating. These cells evidently are taking no part in the formation of the new cells which are crowding amongst the fibres. If any blood-vessels are recognisable, it will be seen that, near the point at which everything is concealed by the leucocytes, they are filled with closely packed blood-corpuscles, indicating the presence

dot. It is in this way that they are closed before, in common with the other ones, they soften and break down in the presence of the invading leucocytes, and thus hæmorrhage is prevented. In this area also, although it cannot be seen with the microscope, the plasma which has exuded from the vessels is coagulated, and with the migrated cells forms a firm substance, the so-called inflammatory lymph, which fills and plugs the spaces of the connective tissue, and thus forms a barrier round the collection of pus, and prevents its diffusing itself amongst the tissues around. It is not possible in a section made from a preparation removed from the body to observe the state of the vessels beyond the area of stasis or thrombosis: but if we could observe them in the living body we should see, in a spreading abscess, all the conditions already described

Fig. 1. Microscopic Abscess in the Skin. *e*, Epithelium; *h*, a Hair; *s*, *s*, Small Vessels surrounded by migrating leucocytes; *p*, the collection of pus; *s*, Sweat gland; *a*, a small Artery; *dot*. The tissues round the collection of pus are dotted with leucocytes becoming more closely packed as the centre of suppuration is approached.

under Inflammation: viz. from the centre towards the circumference, stasis, coagulation, dilated vessels with retarded flow, adhesion of the corpuscles, and migration, and lastly, simple hyperemia, dilated vessels with increased capacity of flow. Such a collection of pus as is above described is a microscopic abscess; an acute abscess, holding half a pint, differs from it only in size. The extension of the abscess takes place by progressive destruction of the tissues by the same process; and the pus is formed by successive zones of new cells degenerating, becoming separated from each other by fluid, and falling into the cavity. In this way the collection of pus advances towards the surface and finally discharges itself. This "pointing of the abscess," as it is termed, advances most rapidly in the direction of least resistance, probably because the migration of the leucocytes and dilatation of the vessels occur more readily on that side. The whole process is identical with ulceration,

but instead of the discharge being given off superficially as in an ordinary ulcer, it accumulates in the abscess-cavity; an abscess is in fact a cavity enclosed by an ulcer. The zone of tissue in which the process of spreading is taking place was in former times spoken of as the "pyogenic membrane"; but it is evident that there is nothing to which the term "membrane" could properly be applied: the "pyogenic zone" would be a more correct term if any such is necessary. In this pyogenic zone the vessels are dilated and the tissues softened, so that in opening an abscess blood may flow freely from the engorged vessels round the cavity: but it must not be concluded from this that the abscess-cavity is surrounded by a zone of tissue in which new vessels have been formed. During the spreading stage of an abscess, it is destruction of vessels, not new formation, that is taking place; the new formation occurs only during repair, after the pus has been let out.

The method in which pus is formed on mucous surfaces in purulent catarrh has been described with that process.

That all the pus-cells in acute suppuration are derived from the white corpuscles may now be regarded as an established fact. The proof of this is derived partly from the direct observation of the formation of pus, as it has already been described, and partly from the experiments of Cohnheim, Verrecklinghausen, and others. These observers injected aniline blue or cinnabar into the blood-stream of the animal to be experimented on. It had before been shown that when solid matter in a state of extremely fine division is injected into the blood-stream, the white corpuscles pick up the particles in the same way as an amoeba takes its food; and the dark-coloured particles of aniline blue or cinnabar are easily recognised in their substance. A frog having been prepared by the injection of the colouring matter, inflammation of sufficient intensity to cause suppuration was excited; and it was found that, whether it was in a vascular part or in a non-vascular, as the cornea, the pus-cells contained particles of the substance which had been injected.

Lastly, there is the negative observation, that in acute inflammations the original cells of the affected part undergo no change so long as they can be observed; that is to say, before they are concealed by the crowds of migrating leucocytes.

In the case of chronic suppuration from the surface of a healing ulcer the purulent fluid must contain many of the superficial granulation-cells which have perished and been cast off. These, as we shall see in the Chapter on Repair, are probably derived from the original cells of the affected part, and are practically indistinguishable from pus-cells derived from migrated corpuscles. This may, however, be regarded rather as an accident than as a part of true suppuration.

Characters of Pus.—The pus from an acute abscess is an opaque, creamy fluid, thick, smooth, and slightly viscid, of a yellowish-white colour, with in some cases a greenish tinge; it has a faint odour and an alkaline reaction. Its specific gravity is from 1030 to 1040. Its chemical constitution varies slightly in different cases. It contains from 85 to 90 per cent. of water. Dried pus contains on an average about 67 per cent. of proteids, chiefly identical with those found in white blood corpuscles, 14 per cent. of fatty matter, half of which is lecithin; about 7 per cent. of cholesterolin, and 10 of extractives, and 2 per cent. of salts. The chief inorganic constituents are sodium chloride, calcium, magnesium, and ferric phosphates; calcium phos-

phate is said to be more abundant in pus coming from bone, but this is doubtful—there is merely a trace of potassium. The serum separated from the corpuscles contains about 90 per cent. of water. Of the solid constituents over 6 per cent. are proteids; not more than '15 per cent. lecithin and other fats; and about '8 per cent. salts, chiefly sodium chloride. It will be seen, therefore, that the lecithin and other fatty matters are chiefly contained in the corpuscles. Pus contains no fibrinogen, but fibrin-ferment has been shown to be present in it. The absence of fibrinogen in pus is most easily explained by supposing that the exudation from the vessels first coagulates in the zone in which the liquid pus has not yet formed, and then softens and breaks down. In addition to the above constituents, peptones and albumoses are found, formed under the influence of the micro-organisms which are constantly present in all acute suppurations. Leucin, tyrosin, and various less important substances are also often found in pus. Pus also frequently contains the specific virus of the disease with which its formation is connected, as in small-pox, glanders, tetanus, soft chancres, gonorrhœa, &c. The organisms specially connected with suppuration will be described later on. Many of the chemical substances found in pus have intense fever-producing (pyrogenic) powers if injected into the blood-stream.

Pus presenting the above characters is termed healthy or laudable pus (*pus bonum et laudabile* of the old writers), but various other terms are employed to indicate different appearances: thus, when tinged with blood it is called *sanguinous*; when thin and watery, *ichorous*; when containing cheesy-looking flakes, *curdy*; and when diluted with mucus, *mucopus*. Besides these, pus presents other varieties; thus, for instance, when it is formed in the brain it is of a greenish tint, and when in the neighbourhood of the alimentary canal it has a peculiar, fetid odour.

Pus is a liquid which readily putrefies when exposed to the air or mixed with water at the temperature of the body, or even if septic organisms be introduced subcutaneously, as by an aspirator-needle or trochar. Thus we occasionally see that a collection of pus which, when tapped for the first time, is free from putrefaction, becomes offensive in a few days unless proper antiseptic precautions are taken during the operation. In some rare cases the pus, soaking a dressing, assumes a distinctly blue colour from the development in it of a special form of organism, the bacillus pyocyaneus. Blue pus is never found in a freshly opened abscess.

Microscopic Characters.—Pus consists of corpuscles floating in a clear fluid, the "liquor puris." In pus drawn from an acute abscess or from the surface of a healthy granulating sore, living cells, presenting amœboid movements if examined on a warm plate, and dead cells which have undergone degenerative changes, are met with, the latter being the true pus-cells, and by far the more abundant. The living cells are mono-nucleated and poly-nucleated leucocytes, and have already been described (*see* Migration of the Leucocytes). The typical "pus-cells" are the dead or degenerating leucocytes. These are rounded in form and slightly irregular in outline, and measure about $\frac{1}{10}$ of an inch in diameter, and their protoplasm is coarsely granular, so that the nucleus is completely concealed. By treating with dilute acetic acid the granules are to a great extent dissolved, the protoplasm becomes swollen, and the nucleus comes clearly into view. It is then seen to be composed usually of three, sometimes of four or two parts, usually devoid of nucleoli

abundant that sometimes the mass is mistaken for a solid tumour. In bone, the enclosing tissue is composed of very dense osseous tissue. Pointing becomes impossible, and such an abscess may exist for an indefinite time. This form of abscess is met with in its most typical form in the mamma. One of the most acute forms of suppuration met with, leading very rapidly to the formation of large abscesses, is the disease known as Acute Necrosis of Bone. Here the pus forms under the periosteum, stripping it extensively from the bone, and finally perforates it, extending to the superficial tissues. The *staphylococcus aureus* or *albus* is constantly present as the cause of the disease. Now in this disease we not uncommonly get examples of abortion of the acute process. The severe constitutional and local symptoms subside, the process becomes chronic, and it may not be for some weeks that an abscess reaches the surface, at the bottom of which dead bone is found, surrounded by a large mass of newly-formed osseous tissue. It has not yet been proved that this is due to death of the micro-organism, either from the triumph of the living tissues over the invading micrococcus or from the development of some chemical substance fatal to it, but it is the probable cause of the mitigation of the symptoms. In one such case examined in University College Hospital no organisms could be cultivated on potatoes.

Abscess formation may also be more or less chronic owing to the feeble virulence of the organism causing the suppuration. The *micrococcus pyogenes tenuis* has been found only in abscesses running a subacute course.

The constitutional symptoms which have already been described (p. 249) correspond in severity to the acuteness of the process.

Situation, Size, &c.—Abscesses are met with in all *regions* of the body, but more especially where the areolar tissue is abundant and the lymphatic glands are numerous. They may occur at any *period of life*, from the earliest infancy to old age. I have opened a very large abscess in the axilla of a child about a fortnight old. Their *size* varies from that of a pin's point to that of a tumour containing a pint or more of pus.

The **Pressure effects** of an abscess are often important. By pressure on the nerves of a part it may give rise to severe pain referred to the nerve and its terminal branches. In deep-seated chronic abscesses this is often a most important element in diagnosis, and from want of attention to it many cases of lumbar and psoas abscess are treated as lumbago or sciatica till the abscess makes itself evident to the most superficial observer. Large veins are often pressed upon and obliterated, but this is very rarely the case with arteries. Abscesses rarely perforate large vessels, even when they are in close contact with them. This accident will be described at the end of the chapter.

Diagnosis.—The diagnosis of abscess, though usually easily made, at times requires close attention. The Surgeon believes that an acute abscess is about to form when, perhaps after a rigor and some increase of the inflammatory fever, he finds the local signs characteristic of the formation of pus; more especially a throbbing pain in the part, with softening of any induration that may have existed, and oedema of the areolar tissue covering it. His suspicion is turned into certainty, and he knows that an abscess has formed, when, after the occurrence of these symptoms, fluctuation can be felt. Fluctuation is the sensation felt by the Surgeon on placing both hands, or one or more fingers of each hand, as the case may be, with moderate firmness upon the part in which the fluid is situated, and then increasing the pressure with each hand alternately.

interest attaching to the subject is so great, that it may be well here briefly to describe the process. The reagents required are, a solution of methyl-violet (one of the aniline dyes), of the strength of half a grain to one ounce of distilled water, carefully filtered, and some pure Canada balsam, which has been heated to drive off its volatile oil. The method of observation is as follows: Spread the pus on a glass cover-slip in the thinnest possible layer, and dry it carefully over a spirit-lamp, taking care not to overheat it: dip a clean glass rod in the methyl-violet solution, and spread a thin film of the dye over the dried layer of pus: after from thirty to sixty seconds, wash the dye off carefully with a gentle stream of distilled water. A darkly-stained film should remain behind, which must be again dried over the spirit-lamp: then while the cover-slip is still warm, put on it a drop of the Canada balsam, warmed fluid by heat, and place it quickly on a glass slide which is also slightly warmed: squeeze it gently down, and when cold it is ready for examination. The micrococci are distinguished from other granules by their definite round form and uniform size, and by their arrangement in groups or chains. They, moreover, take the dye readily, while fatty and albuminoid granules remain uncoloured. Blood or urine may be examined by the same process.

There are, of course, many other methods of staining and preparing organisms, but the above will be found practically efficient for the ordinary pyogenic organisms.

The Chief Micro-organisms connected with Acute Suppuration.—In about 70 per cent. of all acute subcutaneous suppurations the organism present is a micrococcus (see p. 178) belonging to the group *Staphylococcus*, so named from the separate cells being heaped together in irregular masses resembling a bunch of grapes (Fig. 100). *Staphylococci* grow well at ordinary temperatures on

Fig. 100.—Pus from Acute Abscess, containing the *Staphylococcus pyogenes*.

nutrient gelatine, agar-agar and potatoes. When grown on gelatine they gradually liquefy it, and at the same time a slightly sour smell is given off. They generate no gas in their growth, and can either derive the oxygen from the air or from the tissues or fluids in which they may be growing in the body, that is to say, they can be aerobic or anaerobic, according to circumstances. Two chief varieties are commonly met with, *Staphylococcus pyogenes aureus* and *albus*. They are only distinguished by their growth on the various culturing media, the *aureus* forming colonies of a golden-yellow colour, and the *albus* forming opaque white patches. The two forms are frequently found together in the same abscess, and are probably mere varieties of the same species. In rare cases another variety forming lemon-coloured colonies has been met with, and has received the name of *Staphylococcus pyogenes citreus*. The *staphylococci* give rise to localised suppurations, and show no tendency to extend themselves widely by the lymph spaces. On the other hand, they frequently penetrate the small vessels of the part in which they are growing, and

may thus be disseminated through the body, giving rise to one form of pyæmia. Their presence has been demonstrated in pustules and boils upon the skin, in subcutaneous acute abscesses, in empyema, acute suppuration of joints, in acute necrosis of bone, and in suppurating wounds. They have been found in the air, especially of hospital wards, and in dirty water, and they are amongst the numerous organisms met with on the healthy skin.

In about 16 per cent. of all acute suppurations, another micrococcus, the *Streptococcus pyogenes*, is met with. It is so called from the fact that the separate cells tend to arrange themselves in chains usually of from four to ten or more links, but with them separate cells or two together are also found. This organism exactly resembles in every respect that found in cutaneous erysipelas—the *streptococcus erysipellatis*—and the question of their identity will be discussed in the chapter on Erysipelas. It grows on gelatine at ordinary temperatures, forming small punctiform colonies; but it does not liquefy the gelatine. It generates no gas in its growth, and is aerobic or anaerobic according to circumstances.

Fig. 91.—Pus containing the *Streptococcus pyogenes*.

The streptococcus is met with in diffuse suppurations, such as that occurring in phlegmonous erysipelas. It tends to spread widely by the lymph spaces, and has no tendency to invade the vessels, but it may enter the blood through the blood-stream, and is met with in some cases of pyæmia, especially those following labour or operations on the urinary organs. Chain-shaped micrococci are very commonly present in foul urine and in putrid fluids generally, but their identity with the streptococcus has not been proved. Streptococci and staphylococci are found together in about 5 per cent. of all suppurations.

The staphylococci and streptococci account for about 91 per cent. of all acute subcutaneous suppurations. The following are the most important of the other organisms that have been met with:—

The *Micrococcus cereus*, an organism without regular arrangement of its individual cells, forming, when cultivated on gelatine, a waxlike layer, has been described by Passet, but its pyogenic properties are doubtful.

The *Micrococcus pyogenes tenuis*, a very small organism without regular arrangement, first discovered by Rosenbach in a somewhat chronic abscess.

The *Micrococcus tetragenus*, very commonly found in human sputa, especially in cases of phthisis with cavities in the lung. It has also been met with in subcutaneous abscesses and gum-boils. It derives its name from its tendency to divide into four cells, which become surrounded by a gelatinous, transparent envelope.

The *Bacillus pyogenes fetidus* is a very short rod-shaped organism, the length of which is about double its breadth. It can be cultivated on gelatine, which it does not liquefy, and produces foul-smelling gases in its growth. It has been found in foul-smelling abscesses near the rectum, in the brain, and in the gums.

The *Pneumo-bacillus* of Friedländer, an organism found in some cases of

acute lobar pneumonia, has also been met with in acute abscesses in the brain, joints and other parts usually in connection with pneumonia. It forms short rods, or sometimes chains surrounded by a clear capsule soluble in alkalis.

The above are the chief "pyogenic organisms" met with in surgical practice. The *Bacillus pyocyaneus*, or the organism of blue pus, is met with only on dressings, or in discharges from open wounds.

Many other organisms besides the above mentioned possess pyogenic properties, such as the micro-organism of gonorrhœa—the gonococcus—the bacillus of glanders, etc. These will be described with the diseases with which they are associated.

The proof of the Pyogenic properties of Micro-organisms.—The proof of the pyogenic properties of micro-organisms is derived, first, from the constant association of micro-organisms with suppuration; and secondly, from the experimental inoculation of the organisms, cultivated out of the body for several generations in order to get rid of any contamination from the fluid or solid constituents of the original pus. The results of these experiments have varied with the mode of inoculation, the quantity injected, and the animal experimented on.

Simple inoculation of the staphylococci on the skin in animals is usually without result. Subcutaneous injection of a cultivation made into an emulsion with a sterilised fluid produces abscesses in guinea-pigs, rabbits, dogs and mice, but in order to obtain this result it is necessary to inject a sufficient quantity. A small quantity, that is to say, a limited number of the organisms, can be destroyed by the living tissues, and consequently, though a limited inflammation and exudation may take place, an abscess is not formed. Intravenous injections, if in sufficient quantity, cause rapid death with symptoms similar to those of septic poisoning, and after death the presence of the organisms in the blood has been demonstrated. A smaller dose may be fatal in a few days, and on examining the animal after death, small vessels in many parts of the body, especially in the kidney and spleen, may be found to be plugged with masses of the micrococci round which small collections of pus may form. In some experiments, though not constantly, suppuration has been induced in subcutaneous injuries, such as fractures, by injecting the organisms into the blood-stream after the injury has been inflicted. In man, small subcutaneous abscesses have frequently been caused by the inoculation of the micro-organisms, and Garro excited acute inflammation with the formation of a large crop of boils on the skin of his arm by rubbing into it a gelatine cultivation of the staphylococcus aureus derived from a case of acute necrosis of bone. These results have clearly proved the pyogenic properties of the micro-organisms above mentioned.

The Mode of Action of the Micro-organisms in causing Suppuration.—The first step in the process of suppuration is that the pyogenic organism shall find its way to the part, which is most commonly previously damaged in some way. In an open wound the organisms may, as before stated, find their way in from the air, or from impure water, but it cannot be too strongly insisted upon that pyogenic organisms are in all probability constantly present on the surface of the patient's skin and on the Surgeon's hands, and that the thorough disinfection of these by soap and water, followed by an efficient chemical antiseptic, is the most important step in the prevention of suppuration. When suppuration takes place subcutaneously, the organisms find their way to the

part by the blood or lymph-stream. In the former case they may enter by the air passages or alimentary canal, or occasionally from another centre of suppuration, either directly or by the lymphatics. The distribution of the organisms by the lymphatics from a primary centre of suppuration is seen in the suppuration of the lymphatic glands so common in poisoned wounds, and chancre, &c.

The organism having then effected a lodgment damages the surrounding tissues, probably in all cases chiefly by the chemical products formed in its growth, and thus sets up the process of inflammation, which must be regarded as the defensive reaction of the part against the invading pathogenic fungus. The chemical irritant acting upon the tissues, as described in the chapter on Inflammation (p. 174), suspends their vitality, or, in other words, damages them in proportion to its intensity. In order that suppuration may take place, this damage must be of a certain degree, and persist for a sufficient time. The first effect is to cause the ordinary signs of dilatation of the vessel with retarded flow and exudation with migration of leucocytes, which move towards the spot invaded by the micro-organisms. This movement towards the organisms is explained most commonly by the theory that the products of their growth exert an attractive influence on the amoeboid cells—possibly chemiotaxis (p. 161). If the inflammation quickly subsides and a return to health takes place, it is believed to be due to destruction of the invading organisms. How this is effected is a matter which at the present time is giving rise to much discussion, and cannot be regarded as by any means settled. That the organisms are frequently found in the substance of the migrated cells is undoubted. They are found both in an active state and degenerating as indicated by the readiness or difficulty with which they stain. That sometimes they appear to multiply in the phagocytic cell, and causing its death, is also certain. According to Metchnikoff and his followers the whole process of migration is conservative, and the migrated cells act as phagocytes seize upon the invading micro-organisms, take them into the substance and destroy them by intracellular digestion. In the struggle many of the defending cells may perish from the action of the chemical products of the organisms, and from overcrowding and want of nutrition, and these form the dead pus-cells. This view, which looks upon the phagocytes as the chief if not the only protectors of the body against the invasion of pathogenic fungi is opposed by many pathologists, of whom Buchner may be considered the chief. They maintain that the phagocytes are engaged in clearing the tissue of necrotic elements which have perished from the action of the chemical products of the invading organisms, and that when the organisms are found in the migrated cells, they have either been taken up by the phagocytes after they have perished from other causes, or are actively invading the migrated cell which are themselves perishing. They maintain that, when an invading organism perishes, its death is brought about by the chemical action of the fluids of the part. They maintain that the normal blood serum possesses bactericidal properties towards certain organisms, and that chemical substances may be formed, possibly from the breaking up of some of the migrated cells, which are even more potent in killing the organisms or inhibiting their growth. Again, it is not impossible that the organisms themselves in their growth give rise to chemical products which arrest their further growth. Whatever may be the ultimate solution of the question, it

fact remains that, under the influence of the pyogenic fungi, leucocytes crowd the invaded area, and the organisms are found amongst and within the migrated cells. Many organisms which are intensely pathogenic are not pyogenic. For example, the bacillus anthracis, the virus of anthrax or splenic fever, when inoculated on the human subject, invades the tissues, causing gangrene in the infected area, but no pus is formed. In this case the intensity of the irritant is such that all movements of the leucocytes are arrested. In many of the experiments that have been carried out with pathogenic organisms capable of exciting local suppuration, or, under favourable circumstances, of invading the whole body, it has been found that the danger of general infection diminished with the activity of the local process. Thus, Rüffer and Walker found that, on injecting a moderate dose of a cultivation of the bacillus pyocyaneus beneath the skin of a rabbit, abundant migration took place, and the organisms were destroyed locally without any general infection, but if the leucocytes were paralysed by the injection of a sufficient dose of chloral at a distant part of the body, no migration took place, and the animal soon died with the blood teeming with bacilli. In the same way, if a cultivation of a pyogenic organism be mixed with a weak solution of carbolic acid or corrosive sublimate, which has a negative chemiotactic action, that is to say, repels the migrating cells, while at the same time it is not strong enough to kill the organism, no pus will be formed, though there may be some serous exudation, and in the absence of the local defensive reaction, general infection takes place.

Having then got abundant migration and crowds of cells invading the original tissues, taking their place and consuming them where the damage is most intense, the next step is the liquefaction of the intercellular substance and the formation of fluid pus. Here again we have a doubtful point to consider. Does the exudation coagulate as already described in acute inflammation (p. 162), and then soften, or is its coagulation prevented by the presence of some chemical substance, probably peptones, developed under the influence of the micro-organism? It has before been mentioned that pus from an acute circumscribed abscess contains no fibrinogen; on the other hand, peptones are almost constantly present, a fact which may be used to support both theories. Most probably both processes may occur according to circumstances and the nature of the organism causing the suppuration. In the circumscribed acute abscess the lymph spaces round are in all probability plugged with coagulated lymph—at least the microscopic appearances suggest this view—and this is subsequently softened by the action of the micro-organism as the suppuration advances. In the diffuse suppurations, such as in phlegmonous erysipelas, it is probable that the exudation becomes purulent without ever having coagulated. In suppurative pneumonia there can be no doubt that the exudation which is coagulated at first becomes softened and purulent later on.

*On Suppuration taking place in the absence of Micro-organisms?—*It is now generally recognised as a fact that practically all pus with which the Surgeon has to deal is directly caused by the presence of micro-organisms, but experiments have clearly proved that suppuration is possible without their living presence. These experiments have been most frequently carried out by the inoculation of glass tubes or capsules containing the substance to be tested into the subcutaneous tissues by means of an open wound under the strictest aseptic precautions. When the wound has healed by the first intention

and remained sound for some time the capsule is ruptured by pinching it through the skin and the animal killed a day or two after, and the part carefully examined. In many of these experiments there was the obvious fallacy that the substance used was so small in amount and so diffusible that its effect must have been so transient as hardly to be likely to cause suppuration. With other substances, especially sterilised cotton oil, turpentine and metallic mercury, pus was frequently produced in which the absence of organisms was proved both by microscopic examination and by cultivation. Aseptic suppuration has also been induced by the injection of sterilized cultivations of various pyogenic organisms, of putrid fluids, and of some ptomaines derived from them, especially cadaverin and putrescin. Buchner believes that the pyogenic material is often contained in the organisms themselves, and that this may be the case is suggested by the fact that Koch found that the injection of cultures of the tubercle bacillus in which the organism had been destroyed by heat gave rise to suppuration if injected subcutaneously, and that it was necessary therefore to separate the dead organisms in the preparation of the so-called tuberculin.

There is, however, one fundamental difference between the suppuration caused by chemical substances and those in which organisms are present. The former are not progressive, as the pyogenic virus does not increase in quantity; the latter are progressive.

Mechanical irritants, such as tension and friction of surfaces against each other, were formerly credited with the power of causing aseptic suppuration, and many cases of the formation of pus in an ill-drained wound were explained in this way, but as our methods of detecting micro-organisms have been perfected it has been proved that in such conditions micro-organisms are always present. That when suppuration is established these sources of irritation increase the formation of pus is, however, a fact which few practical Surgeons can doubt. In the extreme tension caused by the subcutaneous rupture of an aneurism or a large vessel inflammation and suppuration not uncommonly occur beneath the unbroken skin, but no case of examination of the pus for micro-organisms seems as yet to have been recorded.

The presence of a foreign body in the tissues was at one time considered a sufficient cause of suppuration, but experience in the use of silk ligatures has proved that this is not the case, and that the presence of micro-organisms is the true cause of suppuration in such cases.

The influence of chemical substances in the formation of pus is very evident in granulating wounds, as, for instance, a healthy granulating sore of the leg. If the patient be put to bed with the leg elevated, to avoid intravascular tension, and the raw surface be rendered perfectly aseptic, and then covered by a non-irritating substance, and protected from mechanical violence and cold by an application which at the same time absorbs the discharge and prevents its putrefaction, every source of irritation being thus removed, we may succeed in completely preventing any formation of pus. The discharge such as it is, will be composed solely of serous fluid, which necessarily leaks from the surface of the granulations, as they are uncovered by any impermeable epithelium. Having got the sore into this state, if some mild irritant be now applied, as for example, lint soaked in a concentrated solution of boric acid, the discharge will become turbid, the superficial cells perishing and being cast off under the influence of the irritant, while at the same time

migration takes place from the vessels beneath; if a stronger irritant be applied, as, for example, carbolic acid water (1 in 40) or sulphate of zinc (two grains to one ounce of water), or a 1 per cent. emulsion of creolin, the discharge will become thick pus. Suppose now that a still stronger irritant be applied, as a solution of carbolic acid (1 in 20), or the discharge be allowed to become putrid, the discharge of pus continues and the granulations become soft and swollen from exudation of blood-plasma into their substance. If a stronger irritant still be applied, as a spirituous solution of carbolic acid, the superficial cells perish, forming a slough, and the migration of leucocytes towards the surface is arrested, and all discharge of pus consequently ceases.

*Can simple Septic Organisms—Saprophytes—give rise to Suppuration?—*It has already been stated that various ptomaines, cadaverin, putrescin, &c., have been proved to be capable of causing the formation of pus without the presence of living organisms. It seems almost certain, therefore, that the products of putrefaction are capable of causing suppuration, and this view is confirmed by clinical experience. If an abscess be opened, and putrefaction of the discharges be prevented, the discharge of pus ceases almost immediately, but if putrefaction take place suppuration continues, the discharge being very abundant. It seems impossible to doubt that the chemical products of putrefaction here act as pyogenic agents.

The Accessory Causes of Suppuration.—That the formation of pus is promoted and increased by anything that irritates the tissues seems beyond question. Every practical Surgeon knows that in a suppurating joint movement increases the discharge. Tension, though probably not in itself capable of causing suppuration, is, by the damping influence it exerts on the surrounding tissues, one of the chief causes of the persistence of suppuration in an unopened abscess. It probably diminishes the power of resistance of the tissues to the invasion of the pyogenic organisms. In spreading suppurations such as phlegmonous inflammations, free incisions, relieving tension, frequently arrest the progress of the disease at once. The organisms are still present, but the resistance of the tissues is increased by the relief of tension.

Any constitutional condition which weakens the patient also predisposes to suppuration.

The **Duration** of suppuration necessarily varies greatly. In wounds which fail to heal by primary union, pus usually appears about the third day, but it may be delayed beyond that time. When once established it continues as long as the cause persists; thus an ulcer of the leg or a sinus leading to loose bone, or a chronically inflamed mucous membrane, may discharge pus for many years.

SYMPTOMS OF SUPPURATION.—These are local and constitutional, and necessarily differ according as the process is deep or superficial, acute or chronic.

The *Local Symptoms* of subcutaneous suppuration giving rise to the formation of an abscess will be described further on (p. 252). In chronic superficial suppuration from a granulating sore, the discharge of pus is practically the only symptom.

The *Constitutional Symptoms* of suppuration also vary greatly, according to circumstances. The formation of an acute abscess of any kind is always accompanied by fever. The nature of inflammatory fever and its probable causes have been already discussed (p. 193). In acute suppuration the fever is

ULCERATION.

CHAPTER VI.

ULCERATION.

Ulceration is a progressive destruction of the tissues, in which the solid parts seem to melt away into a liquid discharge without the separation of the portions of dead tissue. The meaning of the term will be made more clear by a few examples. If a piece of skin be killed, as by a caustic, or by mechanical violence, there is at first no solution of continuity, the dead tissue is everywhere continuous with the living: but within a few hours the phenomena of inflammation manifest themselves in the surrounding living tissues, thus imperfectly marking out the limits of the part that is killed. By about the second or third day the line between the dead and living becomes more clearly defined, the cuticle at the margin of the living part becomes loose, and is raised by fluid beneath it, and at last comes away, exposing a narrow raw surface discharging pus; the living tissues which lie in immediate contact with the dead then seem gradually to melt away into the purulent discharge till a complete solution of continuity is established, the dead part, or "slough," being loosened and finally cast off. This process, by which a slough is separated from the parts beneath, takes place entirely at the expense of the living tissues: it is spoken of as ulceration, and the sore left is called a **simple ulcer**.

The effect produced by the inoculation of the poison of a soft chancre forms another excellent example of ulceration. Within twenty-four hours of the inoculation a small inflamed spot appears, with redness, swelling and itching: by the third day the cuticle is raised by a drop of pus: when the thin epidermis is removed a small red sore is seen, from which pus exudes: this slowly extends, the discharge being purulent, and at no time do any visible portions of dead tissue come away with it; the surrounding tissues show the ordinary signs of inflammation. Such a sore is a **specific ulcer**, the irritant which causes it being a specific poison.

A third form of ulceration, differing essentially from the two preceding, is seen in the later stages of the growth of malignant tumours. Thus an epithelioma commences as a small hard growth, which infiltrates the surrounding tissues. By the pressure of the growth which forces its way into the interstices of the structures which it is invading, the original tissues become absorbed, and the cancer-tissue comes to occupy their place. When the growth reaches a certain size its central parts degenerate, soften and break down, and a loss of substance takes place. As the disease progresses the surrounding tissue becomes invaded and destroyed by the cancerous growth, which in its turn breaks down and melts away superficially. Thus the most extensive destruction may take place. This process is described as ulceration, although here there may be no true inflammation, and the resulting sore is a **malignant ulcer**.

All forms of ulceration have one feature in common: the original

migration takes place from the vessels beneath: if a stronger irritant be applied, as, for example, carbolic acid water (1 in 40) or sulphate of zinc (two grains to one ounce of water), or a 1 per cent. emulsion of creolin, the discharge will become thick pus. Suppose now that a still stronger irritant be applied, as a solution of carbolic acid (1 in 20), or the discharge be allowed to become putrid, the discharge of pus continues and the granulations become soft and swollen from exudation of blood-plasma into their substance. If a stronger irritant still be applied, as a spirituous solution of carbolic acid, the superficial cells perish, forming a slough, and the migration of leucocytes towards the surface is arrested, and all discharge of pus consequently ceases.

Can simple Septic Organisms—Saprophytes—give rise to Suppuration?—It has already been stated that various ptomaines, cadaverin, putrescin, &c., have been proved to be capable of causing the formation of pus without the presence of living organisms. It seems almost certain, therefore, that the products of putrefaction are capable of causing suppuration, and this view is confirmed by clinical experience. If an abscess be opened, and putrefaction of the discharges be prevented, the discharge of pus ceases almost immediately, but if putrefaction take place suppuration continues, the discharge being very abundant. It seems impossible to doubt that the chemical products of putrefaction here act as pyogenic agents.

The Accessory Causes of Suppuration.—That the formation of pus is promoted and increased by anything that irritates the tissues seems beyond question. Every practical Surgeon knows that in a suppurating joint movement increases the discharge. Tension, though probably not in itself capable of causing suppuration, is, by the damaging influence it exerts on the surrounding tissues, one of the chief causes of the persistence of suppuration in an unopened abscess. It probably diminishes the power of resistance of the tissues to the invasion of the pyogenic organisms. In spreading suppurations such as pylemonous inflammations, free incisions, relieving tension, frequently arrest the progress of the disease at once. The organisms are still present, but the resistance of the tissues is increased by the relief of tension.

Any constitutional condition which weakens the patient also predisposes to suppuration.

The **Duration** of suppuration necessarily varies greatly. In wounds which fail to heal by primary union, pus usually appears about the third day, but it may be delayed beyond that time. When once established it continues as long as the cause persists; thus an ulcer of the leg or a sinus leading to diseased bone, or a chronically inflamed mucous membrane, may discharge pus for many years.

SYMPTOMS OF SUPPURATION.—These are local and constitutional, and necessarily differ according as the process is deep or superficial, acute or chronic.

The *Local Symptoms* of subcutaneous suppuration giving rise to the formation of an abscess will be described further on (p. 252). In chronic superficial suppuration from a granulating sore, the discharge of pus is practically the only symptom.

The *Constitutional Symptoms* of suppuration also vary greatly, according to circumstances. The formation of an acute abscess of any kind is always accompanied by fever. The nature of inflammatory fever and its probable causes have been already discussed (p. 193). In acute suppuration the fever is

largely due to the entrance into the blood-stream of the various chemical products of the growth of the micro-organisms which are causing the formation of pus. In acute inflammations the occurrence of suppuration is usually marked by an increase of fever, sometimes accompanied by a rigor, but far more commonly only by slight chills. The temperature rises considerably above normal, reaching 103° F. or 104° F. The evening temperature is as a rule about one degree above that of the morning. This high temperature remains unchanged in a case of simple acute abscess till the pus is discharged either artificially or naturally. It then falls rapidly, and if the cavity be completely drained, soon reaches the normal degree. When the abscesses are merely a part of the general process of blood-poisoning, repeated rigors occur, and although opening the abscesses may relieve the patient, it seldom brings the temperature to a normal point. When suppuration occurs in a recent wound or compound fracture, the fever which precedes it is due in the majority of cases to absorption of septic matter from the raw surfaces; consequently, as granulations spring up and cover them and present an efficient barrier to the entrance of the products of decomposition into the circulation, the fever falls, and this usually occurs coincidently with the full establishment of a thick healthy purulent discharge.

In chronic suppuration from a surface there is no elevation of temperature, and the same may be the case in a well-drained cavity, but some fever is sure to appear in the latter case should any accumulation be allowed to take place.

In chronic abscesses, especially in those due to tubercle, the fever is slight, but almost invariably careful observation with the thermometer will show some slight elevation of temperature. It may not be more than a degree above the normal standard, and that in the evening only, but when present for any length of time it is an important aid in diagnosis.

In chronic suppuration from cavities the condition known as *hectic* is often established, or *albumenoid degeneration* of the liver, spleen, and kidneys may set in.

Hectic is a fever of long duration, always accompanied by progressive emaciation and loss of power. The pulse, which is quick, small and compressible, rises from ten to twenty beats above its normal standard; the tongue becomes red at the edges and tip; the cheeks are often flushed, and the eyes glistening, with dilated pupils; all these symptoms have a tendency to exacerbation after meals and towards evening. Profuse sweating and copious diarrhoea are common, and these discharges often alternate with one another, melting the patient away, as it were, and hence are termed *colliquative*. The debility gradually increasing, the patient rapidly wastes, and at last dies from sheer exhaustion, the conjoined result of fever, malnutrition, and wasting discharges.

The nature of hectic fever is a subject on which there has been much difference of opinion. It does not occur unless there is a chronic discharge of pus from the system, and it was formerly supposed to be due in some way to the exhausting effects of the loss of albumen and the other constituents of pus. There can be no doubt, however, that in most, if not in all, surgical cases hectic is in reality chronic poisoning from the absorption of the chemical products of putrefaction, or some other fermentative change going on in the pus. No hectic occurs so long as an abscess, however large, continues

fascia, as in the axilla, or beneath the fascia lata, may extend through the areolar planes of the part, burrowing widely in various directions. In the medulla or cancellous tissue of bone the pus may be imprisoned by the surrounding dense tissue and be unable to reach the surface.

It is possible that very small collections of pus may become absorbed, and thus the abscess may disappear.

After an abscess has burst or has been evacuated, its walls contract and become corrugated, and the cavity is gradually closed by a process of repair identical with the healing of a wound by granulation (*see* Process of Repair). In some cases, however, the cavity does not completely close, but contracts into a narrow canal forming a sinus or fistula (p. 267).

Acute abscesses arising in various parts of the body, as the viscera, joints or subcutaneous tissue, in consequence of the dissemination through the body of particles of infective material derived from a primary centre of inflammation, and carried by the blood-stream, are termed *Metastatic*, and form the prominent feature of pyæmia, with which they will be described.

In the neighbourhood of the alimentary canal abscesses are occasionally met with containing gas as well as pus. These are termed *Tympanitic* or *Emphysematous*. In some cases this is due to a definite communication with the intestines, but in others this is not so evident. These collections are often resonant on percussion, and sometimes gurgling is very distinct in them.

In all acute abscesses the febrile disturbance described on p. 250 is very marked.

Chronic Abscesses are often called also cold or lymphatic, or, from the tendency of some forms gradually to advance in a downward direction, *gravitation abscesses*. There is no sharp line to be drawn between acute and chronic abscesses. In some cases the process of suppuration, which may be acute at first, may gradually become chronic, and in others a chronic process may at the end become more or less acute. The term *subacute* is sometimes applied to cases between the two extremes.

Chronic abscesses, like the acute, probably arise invariably as a result of the invasion of the tissues by a pathogenic organism, but in the most common form of chronic abscess the ordinary pyogenic fungi are not concerned in the process. The great majority of chronic abscesses are of tuberculous origin, and the most typical form is that so commonly met with in connection with lesions of joints and bones, especially the bodies of the vertebrae. The pathological changes met with in tubercle will be more fully described in the chapter on that disease. It will be sufficient here to state that the invasion of a part by the tubercle bacillus sets up a chronic inflammatory process, leading to the destruction of the original tissues and the accumulation of a mass of new cells surrounding the invading organisms, and round this again is frequently a zone in which, as a result of the irritation, new connective tissue is formed enclosing the cellular mass. In all tuberculous processes the cells enclosing the bacilli tend to undergo fatty degeneration, and thus a

Fig. 92.—Pus from Chronic Abscess.

turbid with cells. The whole process thus merges into gangrene. No sharp line can be drawn between spreading gangrenous inflammation and ulceration, and we call the intermediate conditions by such names as sloughing, gangrenous or phagedænic ulceration.

2. In parts which have long suffered from chronic inflammation, slight mechanical and chemical causes give rise to ulceration.

3. Ulceration sometimes commences in the crypts, or follicles, which open on mucous surfaces, as a consequence of catarrhal inflammation, with accumulation of secretion within their cavities. It leads to the formation of circular depressed ulcers.

4. In some general diseases, accompanied by the formation of vesicles or pustules on the cutaneous surface, ulcers may be left when they burst, as in small-pox, pemphigus, syphilitic rupia, and occasionally in chicken-pox.

5. Any injurious influence, whether chemical or mechanical, which causes the death of a part, necessitates the occurrence of ulceration for the separation of the dead tissue, and the sore so left is an ulcer. Long-continued pressure is a common cause.

6. In some specific cases, as before stated, ulceration is preceded by the formation of a morbid growth, as a syphilitic gumma, tubercle, or a malignant tumour.

Situation.—Ulcers may be situated upon any part of the cutaneous surface as the result of loss of substance from wound or other injury. Syphilitic or strumous ulcers may appear on almost any part either of the skin or the mucous membranes, but they most frequently occur in particular situations, as on the penis, lips, tongue, or rectum. Of all forms, however, perhaps the most common with which we have to deal, is the simple ulcer of the leg, so frequently seen in hospital out-patient rooms. The lower half of the leg is the usual seat of these simple ulcers, the skin of that part being much exposed to mechanical violence, and very prone to congestion from position, from varicose veins, and from its great distance from the centre of circulation. In advanced life, moreover, degenerative changes in the arteries of the leg obstructing the flow of blood are very common. Ulcers that form here are slow in healing, and very likely to recur, because the conditions that led to their formation may still exist: also there is often but a very thin layer of subcutaneous fat between the skin and the tibia, and, consequently, there is a great tendency for the under surface of the scar to adhere to the bone.

GENERAL TREATMENT OF ULCERATION.—In the **Local Treatment** of ulceration, the Surgeon must be guided by the special conditions presented by the ulcer, as presently described; but there are some points which demand attention in all cases. 1. Every source of irritation which could cause inflammation, or maintain it if present, must be carefully removed; for while inflammation is present no proper reparative process can go on. Thus, if the ulceration be due to the presence of a specific poison, as in the case of a soft chancre, this must be destroyed by antiseptic or caustic applications. In simple sores the surface must be preserved from friction, the part must be kept at rest, and the decomposition of the discharges must be prevented by proper applications. 2. The circulation must be maintained in a normal state, both congestion and local anæmia being guarded against; as, without a normal supply and a sufficiently rapid change of blood, the growth of the reparative tissue cannot take place. Constriction must therefore be avoided, and the

fluid they contain is usually thin, flaky and curdy, though in some cases the pus is healthy in appearance. Sometimes they contain masses of a soft yellowish substance, apparently formed of coagulated fibrin entangling the fatty remains of degenerated cells, but more commonly the shreds and flakes are of small size. No micrococci or bacteria are found in the pus of a chronic abscess of this kind, nor can tubercle bacilli be recognised as a rule by microscopic examination. This is probably due to the fact that the bacilli in the contents of the abscess have probably broken up, leaving only their spores, for inoculation experiments on animals show that the virus of tubercle is present in the fluid contents of the abscess. The microscopic examination of the sac usually demonstrates the presence of tubercle. Occasionally, even after an abscess of this kind has reached a considerable size, its fluid contents may be absorbed and the abscess undergo a spontaneous cure, its site being healed, if the opportunity arises of examining it, by some dry cheesy matter enclosed in a dense scarlike mass of fibrous tissue.

The above is a description of the most typical form of the chronic tuberculous abscess, but intermediate forms are met with between it and an acute abscess. In joints, abscesses due to tubercle, especially if rest of the affected part be not ensured, not unfrequently contain thick pus with abundant pus-cells, and the wall is formed of a fungating pulpy mass of granulation tissue. In these it sometimes happens that there is a double infection of the tubercle bacillus and one of the common forms of pyogenic micro-organisms. Again, it sometimes happens that a chronic abscess which has scarcely advanced for months may rapidly increase in size, and be found, on being opened, to contain thick creamy pus. This, also, is probably due in some cases to infection of the cavity with the acute pyogenic organisms.

Chronic abscesses, most frequently due to tubercle, are also met with very commonly in the lymphatic glands, and sometimes in bursæ or in the subcutaneous tissue. As they slowly approach the surface, the skin becomes purple and congested, and finally gives way at one point, allowing the curdy fluid to escape, leaving a cavity beneath the undermined skin which is very difficult to cure.

The so-called *Lymphatic* or *Congestive* abscesses, which are met with in scrofulous individuals, arising often without very evident cause in the iliac fossa, axilla and other places, are probably in most cases tuberculous, arising in connection with some small patch of disease in a bone or elsewhere, which has given rise to no pain or other symptom to draw attention to it, so that the fluctuating swelling may be the first symptom noticed.

In *Actinomyces*, that is to say, the infection of the tissues by a peculiar ray-shaped fungus is another occasional cause of chronic suppuration. (See Actinomyces.) The softening of a *syphilitic gumma* may also form a collection of fluid of the nature of a chronic abscess. (See Syphilis.)

Another very important form of chronic abscess is not uncommonly met with in practice. It arises from an arrest or abortion of the acute process. It is probable that this is caused by the death of the micro-organism after the formation of a definite abscess cavity. The acuteness of the process then subsides, owing to the cessation of the formation of irritating products of the organisms. The presence of the fluid causes a very mild irritation (or stimulation) of the surrounding tissues, leading to an overgrowth of the connective tissue. The fluid thus becomes enclosed in a dense wall of fibrous tissue, so

abundant that sometimes the mass is mistaken for a solid tumour. In bone, the enclosing tissue is composed of very dense osseous tissue. Pointing becomes impossible, and such an abscess may exist for an indefinite time. This form of abscess is met with in its most typical form in the mamma. One of the most acute forms of suppuration met with, leading very rapidly to the formation of large abscesses, is the disease known as Acute Necrosis of Bone. Here the pus forms under the periosteum, stripping it extensively from the bone, and finally perforates it, extending to the superficial tissues. The staphylococcus aureus or albus is constantly present as the cause of the disease. Now in this disease we not uncommonly get examples of abortion of the acute process. The severe constitutional and local symptoms subside, the process becomes chronic, and it may not be for some weeks that an abscess reaches the surface, at the bottom of which dead bone is found, surrounded by a large mass of newly-formed osseous tissue. It has not yet been proved that this is due to death of the micro-organism, either from the triumph of the living tissues over the invading micrococcus or from the development of some chemical substance fatal to it, but it is the probable cause of the mitigation of the symptoms. In one such case examined in University College Hospital no organisms could be cultivated on potatoes.

Abscess formation may also be more or less chronic owing to the feeble virulence of the organism causing the suppuration. The micrococcus pyogenus tenuis has been found only in abscesses running a subacute course.

The constitutional symptoms which have already been described (p. 249) correspond in severity to the acuteness of the process.

Situation, Size, &c.—Abscesses are met with in all *regions* of the body, but more especially where the areolar tissue is abundant and the lymphatic glands are numerous. They may occur at any *period of life*, from the earliest infancy to old age. I have opened a very large abscess in the axilla of a child about a fortnight old. Their *size* varies from that of a pin's point to that of a tumour containing a pint or more of pus.

The **Pressure effects** of an abscess are often important. By pressure on the nerves of a part it may give rise to severe pain referred to the nerve and its terminal branches. In deep-seated chronic abscesses this is often a most important element in diagnosis, and from want of attention to it many cases of lumbar and psoas abscess are treated as lumbago or sciatica till the abscess makes itself evident to the most superficial observer. Large veins are often pressed upon and obliterated, but this is very rarely the case with arteries. Abscesses rarely perforate large vessels, even when they are in close contact with them. This accident will be described at the end of the chapter.

Diagnosis.—The diagnosis of abscess, though usually easily made, at times requires close attention. The Surgeon believes that an acute abscess is about to form when, perhaps after a rigor and some increase of the inflammatory fever, he finds the local signs characteristic of the formation of pus; more especially a throbbing pain in the part, with softening of any induration that may have existed, and oedema of the areolar tissue covering it. His suspicion is turned into certainty, and he knows that an abscess has formed, when, after the occurrence of these symptoms, fluctuation can be felt. Fluctuation is the sensation

Surgeon on placing both hands, or one or more fingers of each case may be, with moderate firmness upon the part in which the abscess is situated, and then increasing the pressure with each hand alternately.

On so doing, if fluid be present a wave will be felt to pass from under the hand which is pressing more strongly, raising that which is applied less firmly. In feeling for fluctuation the Surgeon should always place as large a surface of each hand as possible over the supposed fluid. The fingers should be curved so as to adapt themselves evenly to the part, and the pressure should be gentle and steady. If merely the tips of two fingers be poked into an inflamed part it gives pain to the patient, causing him involuntarily to wince and contract the muscles in the neighbourhood, thus obscuring all definite sensations of fluctuation. In large collections of fluid, as in ascites, one hand may be placed on one side and the opposite side struck a smart blow with the tip of one finger of the other hand, when a sharp impulse will be felt distinctly communicated through the fluid. This method of feeling fluctuation is, however, scarcely ever practicable in the case of an abscess.

Fluctuation may readily be confounded with the undulatory sensation communicated by some tissues from mere inflammatory infiltration into them. This, indeed, is a difference of degree rather than of kind: as pus would make its appearance in the course of a few hours, if the tumour were left to itself. Even without this, certain parts give very deceptive sensations from their natural laxity, as is sometimes the case in the areolar tissue of the nates and thigh. A still more perfect sense of fluctuation is given by a muscle when the hands are applied transversely to its fibres: and, consequently, in all cases it is a rule to feel for fluctuation with the hands applied first along and afterwards across the line of any muscle that may be situated beneath or over the suspected collection of fluid. Many soft solid growths give a sense of fluctuation almost as distinctly as fluid, deceiving even the most experienced. In the case of an encapsuled tumour the distinction can readily be made by pressing on its edge with the tip of one finger. If it is a chronic abscess or cyst, unless it be very tense, the finger goes through the swelling without anything being felt to move; in the case of a tumour the solid edge is felt to roll away. In some rare cases, even when fluid is present, fluctuation may be wanting, as the tension may be too great to allow of a wave being produced in the contents of the cavity. The occurrence of fluctuation alone, however, is not of itself sufficient to determine more than that a fluid exists in the part. The question necessarily arises, is this fluid pure? In the majority of abscesses, the history of the case, the character of the pain, the elevation of the temperature, the previous existence and the continuance of symptoms of inflammation, enable the Surgeon to answer in the affirmative. But if, as in chronic or cold abscesses, there be only obscure evidence of inflammation having existed, and if the swelling be of long standing, the fluctuation being perhaps deeply seated and indistinct, the safer plan will be for the Surgeon to introduce an exploring needle, and to see what the nature of the fluid is: by this simple means many embarrassing mistakes in diagnosis may be avoided.

The tumours with which abscesses may more easily be confounded, are *most soft solid growths* in which there is a high degree of elasticity, giving rise to a species of undulation, as in some soft sarcomata. *Fluid tumours* of various kinds, such as cysts and enlarged bursæ, may also be confounded with abscesses. In these cases the previous symptoms, the temperature, the situation, and the general appearance and feel of the tumour, will usually enable the Surgeon to make a diagnosis; but should any doubt exist, the

AND ABSCESS.

The aspirator may be introduced. The "aspirator" is a syringe in which it is desirable to withdraw a quantity of fluid. The most common form of aspirator is a syringe from which lead two short nozzles. One of these is fitted an india-rubber tube, at the end of which is a needle with a terminal opening. The length of the tube is some three-quarters of an inch or more from the handle. In using the instrument, it should first be disinfected with carbolic acid (1 in 20). By this we disinfect and clean the instrument. To prove that everything is in working order. Both stop-cocks, the piston of the exhausting syringe is raised and released.

Fig. 91. Aspirator, convertible into a Siphon.

a. Brass cylinder. b. Glass at lower end. c. Stop-cock, putting the syringe into connection with the discharge tube at the needle. d. Needle. e. Small cock, opening into a side tube, to be aspirated required.

in its position by giving the handle a quarter turn. The needle is pushed in till its opening is buried beneath the skin, when the stop-cock leading to it is turned on. The vacuum then extends into the needle, and thus he gently and steadily pushed in the direction of the suspected abscess. At the moment its point enters a cavity containing pus the fluid will pass up the syringe. A piece of glass is interposed in the india-rubber tube, so the nature of the fluid can be seen, even if the quantity be small. It is the needle in this way, with the vacuum in it, that forms the core of the aspirator as invented by Dieulafoy, and distinguishes it from the suction trepan.

It avoids the possibility of passing the hollow needle through the collection of pus before the suction is applied, and to detect the fluid. In chronic abscesses, even when a large nec-

used, it often becomes choked immediately by the flakes of cheesy matter floating in the fluid, but this rarely happens before enough fluid has been obtained to indicate its nature.

Fig. 24 represents Coxeter's aspirator, which can be converted, if necessary, into a siphon. One stop-cock *c*, as represented in the drawing, closes both tubes. The piston *A* being withdrawn, and a vacuum so produced, the cock *c* is turned on so that it is parallel to the syringe, and the vacuum is thus put in connection with the needle *D*. While doing this, the small cock at *E* must be closed. If it be determined to use the apparatus as a siphon, the cock *E* must be opened, and the handle of the piston forced down so as to fill the long tube passing downwards from *E* with the fluid already drawn from the cavity. The cock *c* now being turned off, the fluid will continue to flow.

The diagnosis of an abscess having pulsation communicated to it by a subjacent artery from an *aneurism* will be discussed when we come to speak of that disease.

Prognosis.—Abscesses vary greatly in danger according to their nature, situation and cause. Pyæmic abscesses are necessarily very fatal, as they commonly occur in the viscera, and are a part of a most dangerous general infective process. An acute abscess is not in itself a serious disease when it can be opened and properly treated; it becomes serious when situated in an important organ as the brain, lung, or kidney; when so situated as to be likely to burst into one of the large serous cavities, or to implicate a joint; or it may become serious by giving rise to general infection. Chronic abscesses are frequently very serious affections, as they are often associated with progressive tuberculous disease of bones or joints. Their size is another source of danger, especially if the large cavity is allowed to become septic after opening. Death from pyæmia is then very common. The age and state of general health are also important. In old or very feeble persons the pain, fever and discharge, even from a comparatively small abscess, may prove fatal.

TREATMENT.—The treatment of suppuration presents three points requiring attention. The first object should be to prevent the formation of matter; the next to take steps for its evacuation when formed; and the last to endeavour to close the cavity that results. The treatment necessary to prevent suppuration in open wounds, or, in other words, to obtain union by first intention, will be fully described in Chapter IX.

In cases in which there is no open wound, the preventive treatment of acute suppuration is nothing more than the preventive treatment of inflammation already described (p. 204). In chronic inflammations threatening to end in suppuration, the constitutional treatment described on p. 229 is of the greatest importance in preventing its occurrence.

Time of Opening.—In an **Acute Abscess**, the matter should in all cases be let out as soon as its presence is recognised. When this is done, the patient at once experiences great relief; the fever and general irritation subside materially, the free incision not only letting out the pus, but removing tension and relieving pain. The rule of opening an acute abscess early is especially imperative when the pus is formed in the sheaths of the tendons or under turgid expansions where there is much tension; also when it is lodged deeply in the areolar planes of a limb, under the larger muscles, where it has a tendency to diffuse itself extensively. In those cases, likewise, in which pus is lodged in close proximity to a joint or under the periosteum, it

grooved exploring needle or a trochar may be introduced. The "aspirator" is of especial service in cases in which it is desirable to withdraw the contained fluid for examination. The most common form of aspirator consists of an exhausting syringe from which lead two short nozzles with stop-cocks. To one of these is fitted an india-rubber tube, at the end of which is a sharp hollow needle with a terminal opening. The needle should *not* have an eye some three-quarters of an inch or more from the point, as is frequently the case. In using the instrument, it should first be disinfected with a solution of carbolic acid (1 in 20). By this we disinfect and clean the needle, and prove that everything is in working order. Both stop-cocks being closed, the piston of the exhausting syringe is raised and re-

in its position by giving the handle a quarter turn. The needle is pushed in till its opening is buried beneath the skin, when the stop-cock leading to it is turned on. The vacuum then extends into the needle, and this is gently and steadily pushed in the direction of the suspected abscess. At the moment its point enters a cavity containing pus the fluid will pass into the syringe. A piece of glass is interposed in the india-rubber tube, so the nature of the fluid can be seen, even if the quantity be small. It is the use of the needle in this way, with the vacuum in it, that forms the chief feature of the aspirator as invented by Dieulafoy, and distinguishes it from the old suction-trochar. It avoids the possibility of passing the hollow needle completely through the collection of pus before the suction is applied, and failing to detect the fluid. In chronic abscesses, even when a large quantity

used, it often becomes choked immediately by the flakes of cheesy matter floating in the fluid, but this rarely happens before enough fluid has been obtained to indicate its nature.

Fig. 94 represents Coxeter's aspirator, which can be converted, if necessary, into a siphon. One stop-cock *c*, as represented in the drawing, closes both tubes. The piston *A* being withdrawn, and a vacuum so produced, the cock *c* is turned on so that it is parallel to the syringe, and the vacuum is thus put in connection with the needle *D*. While doing this, the small cock at *E* must be closed. If it be determined to use the apparatus as a siphon, the cock *E* must be opened, and the handle of the piston forced down so as to fill the long tube passing downwards from *E* with the fluid already drawn from the cavity. The cock *c* now being turned off, the fluid will continue to flow.

The diagnosis of an abscess having pulsation communicated to it by a subjacent artery from an *aneurism* will be discussed when we come to speak of that disease.

Prognosis.—Abscesses vary greatly in danger according to their nature, situation and cause. Pyæmic abscesses are necessarily very fatal, as they commonly occur in the viscera, and are a part of a most dangerous general infective process. An acute abscess is not in itself a serious disease when it can be opened and properly treated; it becomes serious when situated in an important organ as the brain, lung, or kidney; when so situated as to be likely to burst into one of the large serous cavities, or to implicate a joint; or it may become serious by giving rise to general infection. Chronic abscesses are frequently very serious affections, as they are often associated with progressive tuberculous disease of bones or joints. Their size is another source of danger, especially if the large cavity is allowed to become septic after opening. Death from septicæmia is then very common. The age and state of general health are also important. In old or very feeble persons the pain, fever and discharge, even from a comparatively small abscess, may prove fatal.

TREATMENT.—The treatment of suppuration presents three points requiring attention. The first object should be to prevent the formation of matter; the next to take steps for its evacuation when formed; and the last to endeavour to close the cavity that results. The treatment necessary to prevent suppuration in open wounds, or, in other words, to obtain union by first intention, will be fully described in Chapter IX.

In cases in which there is no open wound, the preventive treatment of acute suppuration is nothing more than the preventive treatment of inflammation already described (p. 204). In chronic inflammations threatening to end in suppuration, the constitutional treatment described on p. 229 is of the greatest importance in preventing its occurrence.

Time of Opening.—In an **Acute Abscess**, the matter should in all cases be let out as soon as its presence is recognised. When this is done, the patient at once experiences great relief; the fever and general irritation subside materially, the free incision not only letting out the pus, but removing tension and relieving pain. The rule of opening an acute abscess early is especially imperative when the pus is formed in the sheaths of the tendons and under fibrous expansions where there is much tension; also when it is situated deeply in the areolar planes of a limb, under the larger muscles, where it has a tendency to diffuse itself extensively. In these cases, likewise, in which pus is lodged in close proximity to a joint or under the periosteum, it

Under this plan of treatment the edges will subside, the surface of the sore will become florid, and granulations yielding abundant discharge will speedily spring up. Much of the success of this plan of treatment will depend upon the close attention that is paid to it. If the skin be irritable, resin plasters should not be used, but merely the soap or lead; and the plasters should be changed at least every forty-eight hours. If the discharge be very abundant, small holes should be cut in the strips to allow it to escape. When by this mode of treatment the edges of the sore have been brought down, and the granulations sufficiently stimulated, an astringent lotion with bandaging may advantageously be substituted for the plasters. The great difficulty in carrying out this treatment in hospital out-patient practice, in which the patient is usually seen only twice a week, arises from the foul state into which the sore gets in the intervals of strapping; it is therefore very important to employ if possible some antiseptic mode of dressing. In order to do this, the first necessary step is to disinfect the sore, which when first seen is usually very foul. This is by no means so easy as might be supposed. It can be done by the free application of chloride of zinc (gr. xx. to 3j.), but this is very painful; another plan is the application of a hot boric acid dressing as before described, changed every four hours, for two days, and this is very efficient if the patient can only be trusted to do it. Perhaps the best plan is to powder the whole surface of the sore with iodoform in crystals; this is efficient, and as a rule painless. When the sore is quite clean it may be dressed as follows: apply a small sprinkling of powdered iodoform, over this place a piece of protective green oiled silk, then strap the limb, heating the strips of plaster by dipping them in a hot solution of carbolic acid (1 in 40), then apply a carbolic gauze bandage from the foot to the knee to protect the skin, over this put a thick pad of carded oakum to absorb the discharge, and over all place a common calico bandage. The improvement that results from this treatment is often most surprising.

Another mode of applying pressure has been introduced by Martin, of New York. It consists simply in the application of a bandage made of pure india-rubber, free from sulphur. The bandage is applied directly to the sore, no dressing being used when it is on. It is worn only by day; and at night some simple dressing, *free from grease*, may be used. The bandage is thus applied: Before rising from bed in the morning, the patient rolls the bandage round the leg, taking care not to pull it in so doing. It must only just lie smoothly on the limb, for any traction might seriously impede the circulation. The patient now rises from bed, and the slight increase in the size of the limb from gravitation of blood into it tightens the bandage sufficiently to make it keep its position. At night the bandage is removed, sponged with warm water, and hung up to dry. The leg must also be carefully washed, and the sore may be dressed with some simple lotion. The only inconvenience of the treatment is, that from the obstruction to the escape of the perspiration, eczema is frequently set up. This is best treated with some oxide of zinc powder, and usually, after a short time, the leg seems to become accustomed to the presence of the bandage, and no further trouble is experienced. This treatment is usually very successful, especially in cases complicated by the presence of varicose veins.

The treatment recommended by Unna of Hamburg, will be found most useful, especially when the ulcer is associated with varicose veins and the

out of a hot solution of carbolic acid (1 in 20) to disinfect the surrounding skin. The incision may be made with an abscess-bistoury, a Syme's sickle-shaped knife or a scalpel. It should be made either at the point where fluctuation is most distinct, or at the most dependent part, so as to prevent subsequent dragging of the matter. The bistoury should be held short, and introduced perpendicularly. If the depth to be reached be considerable, the blade of the bistoury should be half turned round after its introduction, when the pus wells up by its side if the abscess have been reached, the point at the same time being felt to move freely in the cavity of the abscess. The incision must then be continued for a moderate extent in the direction of the natural folds of the skin of the part if possible, and always parallel to the course of the chief vessels. The healing of the abscess cavity without further suppuration is certainly facilitated by cleaning it out. This should not be done with any sharp scraping instrument lest unnecessary injury be done to the surrounding parts softened by inflammation. The cleaning is best effected by means of a piece of sponge, moistened with a solution of corrosive sublimate (1 in 500). A moderate degree of force may be used in order to remove the superficial layers of the wall of the cavity. The cavity must then be dried by the repeated introduction of fresh pieces of sponge squeezed as dry as possible. This scrubbing the wall of an acute abscess necessarily causes some bleeding, and in large abscesses, or in those in very vascular organs, it is often wiser to omit it, but when it can be done without causing loss of blood, it certainly seems to promote rapid healing. Any bleeding that may occur from the wall of the cavity is very easily arrested by elevation and pressure. No antiseptic seems to arrest suppuration better than the strong perchloride solution (1 in 500), but this must only be used with a sponge, and all excess afterwards removed lest it cause poisoning. If it be thought inadvisable to sponge out the cavity, it may be freely irrigated with some antiseptic solution. The introduction of a small quantity of iodoform is often useful in checking further suppuration.

The abscess cavity having been opened, and cleaned if possible, it is usually necessary to make provision for some future discharge. If this be not done, the lips of the wound tend to stick to each other, and the cavity may become quickly distended with fresh fluid. In small abscesses which have been freely opened the introduction of a small piece of lint soaked in some antiseptic lotion for a few hours will suffice, but if the abscess be deeply seated or of large size a drainage tube should be inserted.

Tents made of plugs of lint and metal drainage tubes were frequently used by the old Surgeons in the treatment of suppurating wounds and deep-seated abscesses, but the methodical use of *Drainage-tubes* was introduced into modern surgical practice by Chassaignac in 1855. The tubes should be made of vulcanized rubber, which is the most durable, and should have holes cut in them at regular intervals. They should be kept in a solution of carbolic acid (1 in 20) for at least 24 hours before being used, to render them thoroughly aseptic. They must correspond in size to the capacity of the cavity they are intended to drain: not so much because a small tube could not carry off all the pus that escapes, but because the larger tubes are less likely to get accidentally choked, and the larger the cavity, the more serious would be the consequences of such an accident. A couple of threads, about 2 inches in length, must be sewed one to each side of the superficial end of the tube. These lie upon the skin beneath the dressing when the tube has been inserted, and prevent its

ULCERATION.

...the tender spot should be found, and a knife or lancet point ... to divide the branch of nerve passing to it, a treatment ...

Ordinary Ulcer. This is characterised by redness, swelling, heat, and ... The *edges* are sharply cut. The *surface* is often ... and dry from stasis in the vessels of the granulations, but ... becomes covered with a thin yellow slough. The *base* is swollen and ... the surrounding tissues. The *discharge* is serous and often ... in the most acute stage the surface of the sore may be dry, and ... a thin crust or scab. It arises most commonly in people who ... and is not unfrequently associated with gout. Any sore may, ... become inflamed if neglected and allowed to become covered with ... discharges.

The *treatment* must be both general and local. As a rule, the patients are ... for purging. This may usually be effected by a mercurial pill, after ... sulphate of magnesia, \mathfrak{ss} , infusion of quassia, \mathfrak{z} l., may be given three ... daily for a few days. If the patient be gouty, ten drops of vinum ... may be added to each dose. Locally the limb must be elevated, and the patient kept in the recumbent position. Hot applications will be found always to give the greatest relief. Hot boric acid fomentations in most cases speedily reduce the pain and swelling. Another excellent application is the following: acetate of lead, \mathfrak{ss} ; tincture of opium, \mathfrak{ss} ; water, to \mathfrak{vi} ij.; pour a small quantity of the lotion into a saucer and add an equal quantity of boiling water; moisten with this diluted lotion a piece of lint of sufficient size to cover the whole reddened area; apply it warm and cover it with oiled silk, then wrap the whole part in a sheet of cotton-wool. We thus get warmth and moisture, with a powerful astringent and sedative, and experience has shown that the quantity of acetate of lead present is sufficient to prevent any decomposition of the discharges. If preferred, tincture of belladonna may be substituted for the tincture of opium.

Sloughing Ulcer.—When not specific, this is an increased degree of the inflamed variety, usually occurring in feeble or cachectic states of the constitution, and generally accompanied by a good deal of fever. The *surrounding skin* presents an angry, dusky, red blush; the *edges* are sharply cut; and the *surface* is covered with a greyish slough. The *discharge* is serous and offensive; there is a sense of heat and pain, and the inflamed area is acutely tender. The ulceration, unless arrested, spreads rapidly.

Treatment.—The general health must be improved by a nourishing but unstimulating diet, combined with the use of tonics. Opium is of the greatest value. One grain should be given twice or thrice daily. The patient must be kept in bed, and the part elevated. If the surface of the sore be very foul, it may be sprinkled with iodoform, after which hot fomentations must be applied to the whole reddened area. As the inflammation becomes less acute, the warm lead and opium lotion above mentioned may be applied, and when the sloughs have separated, and the surface has become clean, the ordinary treatment of a healthy sore must be adopted. (See Gangrene.)

A special form of sloughing ulcer is not uncommonly met with in patients ... from diabetes. It commences sometimes as a bleb, which bursts and ... a brown slough, including the whole cutis, but not extending ... subcutaneous tissue. The slough may very gradually extend,

through the substance of the muscle into the cavity of the abscess, and along the groove of this a slender pair of dressing-forceps is passed : when it reaches the abscess the blades are opened up, the muscular fibres separated, and free exit given to the pus. The opening thus made must be maintained by the insertion of a drainage-tube, or the patient's condition will be but little improved, as the muscular fibres come together again as soon as the dressing-forceps are removed, and proper drainage being thus rendered impossible, the pus will soon re-accumulate, and may decompose and give rise to septic poisoning.

After the opening has been made the cavity left eventually fills up either by the confluence of the sides or by granulating from the bottom. If from the situation of the opening the cavity does not drain properly but becomes partly filled again with pus, a fresh incision, termed a "counter-opening," may require to be made in the most dependent part.

The treatment of the abscess from the time it is opened till the cavity is closed, is best carried out by the application of some efficient absorbent antiseptic dressing. Any of those mentioned in the preceding Chapter and in that on the Treatment of Wounds may be used.

In cases of acute diffuse suppuration in which it may be wished to continue the application of warmth and moisture after the incision has been made, compresses of boric acid lint or of salicylic wool will be found most useful. In situations in which it is difficult to apply an efficient antiseptic dressing, as at the margin of the anus, the introduction of a small quantity of iodoform into the cavity will usually act as an efficient antiseptic.

Unseed-meal poultices should never be used after an abscess has been opened or has burst. They encourage putrefaction and suppuration, and often become extremely foul when soaked in pus.

Treatment of Chronic Abscesses.—Chronic abscesses may be treated by Tapping or Aspiration; by Aspiration followed by injection of some antiseptic fluid, with or without previous washing out of the sac; by Incision, scraping, and scraping, followed by the injection of iodoform and immediate closure of the wound; by Incision and drainage; and, lastly, by Excision of the sac.

Simple Tapping or Aspiration seldom effects a cure, but may occasionally be adopted as a palliative treatment in very large chronic abscesses, especially when the patient is dying from tuberculous or other chronic disease, or the Surgeon is temporarily placed in circumstances which make more efficient treatment impossible. One tapping will often delay the bursting of the abscess, with its attendant dangers, for many weeks.

Tapping is best done by means of the aspirator, the method of using which has already been described (p. 258). A large needle should be used, as the pus is often too thick to flow through a small one, and even then the operation often fails owing to the presence of curdy matter, which chokes the needle. If any pus has entered the syringe, the needle may sometimes be cleared by forcing some back through the needle, but if it becomes choked again at once, some other method of treatment must be adopted. If the pus comes freely through the needle, the aspiration should be continued as long as it flows, or until it becomes darkly stained with blood. During the aspiration the needle should be kept perfectly steady, to avoid any needless damage to the wall of the abscess, and all squeezing should be avoided, as the pressure of the atmosphere

the ulcer heal, it constantly breaks open again ; or hæmorrhage may occur from a ruptured vein on its surface. Other means, which will be described in a future chapter, must then be taken for the permanent occlusion of the varicose vessels.

Ulcers on Mucous Membranes.—Various forms of ulcer occur upon mucous membranes, especially those of the throat, rectum, and genital organs. As these, however, are commonly specific, they will be described hereafter.

Ulcers of mucous membranes, when not of a specific character, present the general appearances characteristic of the cutaneous healthy, inflamed or weak varieties, and require the topical applications which have been described as suited to these conditions ; though generally they will demand the free employment of caustics, or astringents, especially of the nitrate of silver.

A. E. Barker. Some iodoform emulsion may be injected before the incision is closed with sutures. The flushing and scraping must be performed with care, and the Surgeon must avoid tearing through the bands, which are often felt crossing the cavity, as these may contain vessels of considerable size. The profuse capillary hæmorrhage which sometimes occurs from the wall of the abscess may be arrested by firm pressure.

Incision and Drainage is the mode of treatment which becomes necessary sooner or later in many cases. It should, however, as far as possible, be reserved for cases in which the methods already described are not available or have failed. The dangers attending the opening of a large chronic abscess, should putrefaction of the discharges follow, have already been pointed out. Efficient antiseptic means must be adopted to prevent this accident, and if from any cause this be not possible, the dangers that follow the admission of air may be greatly reduced by making free incisions and inserting large drainage-tubes, so that the quantity of decomposable matter shall be reduced to a minimum.

If a chronic abscess has been opened and, either from neglect of antiseptic

Fig. 96. — Two forms of Volkmann's "Sharp Spoon."

precautions or failure of the means adopted, the discharges become offensive, the patient's life may be endangered either by the profuseness of the suppuration or by the absorption of the products of putrefaction. In these circumstances if the abscess has been opened by a small wound not larger than is required for the insertion of the drainage-tube, it is wiser, if possible, to enlarge the wound, or if this be not possible, to make a free counter-opening. In this way by establishing perfect drainage, the danger of septic poisoning is greatly lessened. At the same time the cavity may be cleaned out with a sponge soaked in a solution of chloride of zinc (40 gr. to 5j.), and the raw surface dusted with iodoform, after which an antiseptic dressing may be applied. It is possible sometimes in this way to render the cavity perfectly aseptic. The immediate effect of this proceeding is usually to cause an elevation of temperature, soon followed by a permanent fall. This mode of treatment is specially applicable to chronic abscesses connected with joints.

If the cavity be of great size and deeply situated as in the case of a psoas or ischiatic abscess, complete disinfection is extremely difficult. The abscess may be washed out by injection of some antiseptic solution, such as Condy's fluid, carbolic acid lotion (1 in 40), corrosive sublimate (1 in 2000), or boric acid, and by this means the offensive smell of the discharge may be diminished; but the suppuration is kept up, or even increased, by the repeated application

of these irritating fluids, and at the same time, if they are discontinued, the signs of putrefaction soon return. Callender pointed out that this is in many cases due to the irregularity of the cavity and the impossibility of making the antiseptic reach every part of it, and he therefore recommended that the fluid should be pumped in at some degree of pressure, so as completely to distend the sac. After this has been done, some antiseptic dressing may be applied. The injection must be done under an anæsthetic, so as completely to relax the parts round the abscess. This treatment has been followed by very good results. The solution Callender used was the 1 in 20 carbolic lotion diluted with half its bulk of hot water. A very dilute solution of iodine has also been used with good results. Chloride of zinc, 40 grains to the ounce of water, has been employed for the same purpose; but it is a dangerous remedy, as in that strength it is powerfully caustic and can be safely applied only with a sponge as above described. In injecting an abscess-cavity with any antiseptic solution, great care must be taken not to use too much force, or the sac may be ruptured and the fluid diffused in the areolar tissue, an accident which might be fatal, especially if the stronger antiseptics were being used. Another plan recommended, is to introduce iodoform into the cavity by means of a brush, or on the end of the drainage-tube, or by injecting it as an emulsion with glycerine and water. It must not be forgotten, however, that iodoform dissolves very slowly and adheres to the wall of the abscess, so that if some is introduced daily, it may accumulate until a quantity is present sufficient to give rise to symptoms of poisoning. A case of this kind occurred in University College Hospital, which nearly proved fatal before the cause of the strange symptoms from which the patient suffered was discovered and removed.

Excision of the whole abscess wall, when such treatment is possible, is undoubtedly the best mode of curing many chronic abscesses. In the chronic mammary abscess the removal of the thick fibrous wall greatly hastens the cure. In tuberculous abscesses the same treatment is often possible, as in those connected with joints and superficial bones. The removal of the sac of the abscess is most easily done by careful dissection with forceps and scalpel or scissors, the part being made bloodless by Esmarch's method. The bleeding is easily arrested by pressure and elevation of the limb.

Constitutional Treatment of Suppuration.—With the view of preventing the occurrence of suppuration, the Surgeon must be careful to maintain the powers of the system, and not to reduce the patient too much, even if the inflammation be of an acute character at the outset. Suppuration is a condition of debility, and is especially predisposed to by any previously existing enfeebled state of the system, or by malnutrition. Another reason for the avoidance of the early employment of debilitating means is that, if suppuration once be established, the drain on the system may eventually be so considerable as to require all the patient's powers to enable him to bear up against it. While the abscess is discharging, nourishing, tonic, and even stimulating treatment will be required in proportion to the amount of debility that is induced. Amongst the most useful medicinal agents are mineral and vegetable tonics, the mineral acids, and cod-liver oil in the more chronic stages. Attention to hygienic conditions, with change of air, and residence at the sea-side, are also valuable. Should hectic come on, the same general tonic plan must be adopted, while we have recourse to means adapted to meet the local

symptoms. Thus, acids are required to check the sweating, astringents to arrest the diarrhoea, and as much mild nourishment as the patient will bear to support the strength.

HÆMORRHAGE INTO THE CAVITY OF AN ABSCESS is not of unfrequent occurrence. It may arise from three sources: 1. Oozing of blood from the vascular wall of the abscess; 2. Ulceration into a vein; 3. Ulceration or sloughing of the coats of a neighbouring artery.

The **bleeding** which occurs **from the abscess-wall** is the most frequent, and the least important. It sometimes takes place before the abscess is opened, the pus that escapes being then found to be sanious and mixed with small coagula. More commonly it occurs after the opening of the abscess, in consequence probably of the wall having lost the support of the contained pus, when the vessels in the soft tissues give way and the cavity speedily fills with blood. In these cases the hæmorrhage may be arrested by laying the cavity of the abscess freely open and turning out the coagula, when the bleeding usually ceases as soon as the interior is exposed to the cold air. Should this fail, it may be necessary to stuff the cavity with some antiseptic material as iodoform- or salicylic-wool, and to apply pressure with a bandage. When the cavity is closing, the vascular granulations which form upon its walls may bleed very freely if any pressure be accidentally brought to bear on the veins leading from the part. In this case the bleeding ceases immediately the pressure is removed.

Hæmorrhage from **Ulceration extending into a neighbouring Vein**, is necessarily far more serious. It has usually happened from sloughy abscesses, formed in the neck as a consequence of scarlatina in strumous and unhealthy individuals, opening up the internal jugular vein. But it may arise, independently of any specific inflammation, in cachectic patients. In these distressing cases, the only treatment that can be adopted is, to plug the cavity of the abscess. In this way the fatal event may be for a time perhaps delayed; but it is inevitable ultimately, the blood bursting forth by the sides of the plugs as these become loosened, or as the sloughing opens up the vein more widely.

If the hæmorrhage arise from the **Ulceration of a large Artery**, the case necessarily becomes one of extreme urgency. I have known this condition to occur in the neck and in the thigh; in the neck from sloughy scarlatinal abscess implicating the carotid; in the thigh, from the extension of ulceration from abscesses and sinuses to the deep femoral. When this untoward complication of abscess occurs in the neck, the hæmorrhage is usually so sudden and so profuse that the Surgeon has not time to tie the carotid before it is extinguished. A. J. Pepper has, however, recorded a case of severe hæmorrhage after scarlet fever, which was repeated several times, and finally successfully arrested by ligature of the common carotid. The patient was a man, aged 30, and made a good recovery. In the thigh the case is not so urgent. Warnings by repeated small hæmorrhages may have enabled the Surgeon to adopt means to restrain the bleeding; and, in the case to which I allude, that of a young man, the femoral artery was tied successfully.

SINUS AND FISTULA.—After an abscess has been opened, its cavity may not fill up completely; but, contracting into a narrow suppurating track, it may form a canal without disposition to close, from which a small quantity of pus constantly exudes, thus constituting a **Sinus** or **Fistula**.

A *sinus* is a suppurating track penetrating to a greater or less depth into the tissues, closed at its deep end, and opening on the surface of the body. A *fistula* is an abnormal communication between two of the cavities of the body, or between a cavity and the surface, or a track through which the secretions of some gland or hollow viscus takes an unnatural course. Thus we talk of a sinus leading down to dead bone, but of a recto-vesical fistula, an aerial sinus, a urinary fistula, &c.

The *Causes* of this non-closure of an abscess may be referred to the following heads: 1. The presence of a foreign body, as a piece of dead bone; 2. The passage of irritating matters, as urine, feces, saliva, &c., through the abscess; 3. The contraction of neighbouring muscles: as when the abscess is in the neighbourhood of the sphincter ani, and as occasionally happens in abscesses about the limbs; and 4. The presence of an insufficiently drained sinus at the bottom of the sinus.

The orifice of a sinus or fistula when situated in hard and condensed tissue is often very small, depressed, and perhaps covered by a scab. In soft tissue it is commonly large and widely open; when communicating with bone it is usually soft, florid granulations obstructing it.

Structure.—A sinus consists of a narrow channel, often long and winding, having an external orifice usually somewhat protuberant, and situated among loose florid granulations. The walls of this channel, which are always indurated, are lined by a layer of imperfectly-formed granulations exuding pus. If the orifice be occluded, this pus will collect within the sinus, distending its walls, reconvert it into an abscess. In structure, therefore, a sinus may be said to be a long, narrow, chronic abscess, with a permanent external aperture.

The granulation-tissue of a sinus, like that of any other granulating surface, contracts in healing, and consequently a healed sinus leaves a deep depression in the skin. This is the best evidence of thorough healing; a sinus which always be expected to break open again if it skins over superficially without dimpling.

A fistula may differ in no respect from a sinus when its length is considerable, as in many anal and urethral fistulae, but when it forms merely a communicating channel between two cavities, as between the rectum and vagina, or between the surface and a cavity or duct, as in a track of a salivary fistula, the granulations may become completely covered by epithelium continuous with that on each side, and no cure is possible till this has been removed or destroyed.

The **Treatment** of a sinus or fistula has reference to its cause in the first instance; for, until the foreign body or the insufficient drainage that keeps it open and maintains the discharge has been removed, it will be useless to attempt its closure. After the removal of the obstacle to healing, we endeavour to procure obliteration of the sinus by one of three methods:

1. *Pressure*, by means of a roller and graduated compress, so as to bring about the adhesion of its opposite sides, is useful in those cases in which the sinus is recent, without much surrounding induration, and so situated, as upon the trunk, that pressure can easily be applied.

2. A more healthy condition may often be produced in the sinus by irrigating it from time to time with "red wash," or with tincture of iodine, or by the introduction of iodoform in crystals by means of a catheter or by

ligues such as are used in the treatment of gonorrhœa ; by passing a probe coated with nitrate of silver to the bottom ; by inserting a drainage-tube.

3. *Scraping away* the callous and imperfectly granulating sides of the sinus by means of a small sharp spoon (Fig. 96), or destroying them by means of a red-hot wire or the thermo-cautery, is a very efficacious means of setting up a new and healthier action in the part, and so bringing about closure of the canal. The galvanic cautery will often be found most convenient, as the wire can be introduced cold and heated *in situ*, and the danger of wandering from the track of the sinus is thus avoided.

In many cases, scrubbing with a sponge soaked in a solution of chloride of zinc (40 gr. to 3j. i. and held in a pair of forceps, is very useful.

4. The last method consists in *laying open the sinus* from end to end, and then dressing the wound so that it may heal from the bottom ; in this way neighbouring muscles, that have kept it open by their contractions, may also be set at rest. The division of the sinus should be made with a probe-pointed bistoury, introduced through the external opening either by the aid of a director or without such assistance. The operation should be done effectually, the sinus being followed as far as is prudent, and laid open as completely as possible. Some fistulæ, as the fistula in ano, require similar treatment.

5. Fistulæ which are lined by a complete epithelial covering, as many recto-vaginal, recto-vaginal, and recto-vesical fistulæ, can be cured only by destroying this, either by cutting or scraping it away, or by cauterisation. Many such fistulæ require plastic operations for their cure.

CHAPTER VI.

ULCERATION.

Ulceration is a progressive destruction of the tissues, in which the solid parts seem to melt away into a liquid discharge without the separation of visible portions of dead tissue. The meaning of the term will be made more clear by a few examples. If a piece of skin be killed, as by a caustic, or by mechanical violence, there is at first no solution of continuity, the dead tissue is everywhere continuous with the living; but within a few hours the phenomena of inflammation manifest themselves in the surrounding living tissues, thus imperfectly marking out the limits of the part that is killed. By about the second or third day the line between the dead and living becomes more clearly defined, the cuticle at the margin of the living part becomes loose, and is raised by fluid beneath it, and at last comes away, exposing a narrow raw surface discharging pus; the living tissues which lie in immediate contact with the dead then seem gradually to melt away into the purulent discharge till a complete solution of continuity is established, the dead part, or "slough," being loosened and finally cast off. This process, by which a slough is separated from the parts beneath, takes place entirely at the expense of the living tissues: it is spoken of as ulceration, and the sore left is called a **simple ulcer**.

The effect produced by the inoculation of the poison of a soft chancre forms another excellent example of ulceration. Within twenty-four hours of the inoculation a small inflamed spot appears, with redness, swelling and itching; by the third day the cuticle is raised by a drop of pus: when the thin epidermis is removed a small red sore is seen, from which pus exudes: this slowly extends, the discharge being purulent, and at no time do any visible portions of dead tissue come away with it; the surrounding tissues show the ordinary signs of inflammation. Such a sore is a **specific ulcer**, the irritant which causes it being a specific poison.

A third form of ulceration, differing essentially from the two preceding, is seen in the later stages of the growth of malignant tumours. Thus an epithelioma commences as a small hard growth, which infiltrates the surrounding tissues. By the pressure of the growth which forces its way into the interstices of the structures which it is invading, the original tissues become absorbed, and the cancer-tissue comes to occupy their place. When the growth reaches a certain size its central parts degenerate, soften and break down, and a loss of substance takes place. As the disease progresses the surrounding tissue becomes invaded and destroyed by the cancerous growth, which in its turn breaks down and melts away superficially. Thus the most extensive destruction may take place. This process is described as ulceration, although here there may be no true inflammation, and the resulting sore is called a **malignant ulcer**.

All these forms of ulceration have one feature in common: the original

tissues are first infiltrated by cells foreign to the part, which destroy them and occupy their place; then in their turn the new cells perish, and are thrown off superficially with a fluid discharge, and thus a progressive destruction of tissue takes place. In the first two examples the invading cells are the leucocytes which have migrated from the blood vessels, and in the last they are the special cells of the malignant growth.

In the present chapter we have to deal only with ulceration as it occurs as a part of the process of inflammation.

An ulcer passes through two stages, viz. 1. Extension; and 2. Repair. To the former of these only is the term "ulceration" applied.

PATHOLOGY.—The process of ulceration when dependent on inflammation hardly needs a detailed description, as it differs in no essential feature from that already described as taking place in the formation of an abscess, the only variation being that in the latter case the formation of pus and destruction of tissue take place in a closed space, while in the former they occur upon a surface. The separation of a dead piece of tissue from the surrounding living parts is thus accomplished. The tissue immediately in contact with that which is dead must necessarily have suffered to some extent from the injury which has caused the mischief, and its vitality thus being lowered, the phenomena of inflammation are manifested in it with an intensity corresponding to the degree of damage, and consequently diminishing as we recede from the parts that have been actually killed. Where the living tissues touch the dead the condition of stasis will be reached, and those vessels which pass from the dead to the living tissue will become plugged with clots extending as far as the next branch in the living parts. Beyond the area of stasis we find that of retarded flow, accumulation of leucocytes, and migration; and, beyond this again, that of simple dilatation with increased rapidity of flow. The width of the area in which these inflammatory phenomena take place varies greatly. It may be merely microscopic, as in the separation of a piece of dead tissue which has been prevented from decomposing by antiseptic treatment, or it may extend for half an inch or more. Occasionally these vascular conditions can be recognised clinically by the effect produced by the pressure of the finger; in the area of fluxion it is scarcely possible to remove the finger before the brilliant red colour has returned; in that of retarded flow a second or more may elapse before the pale mark made by the finger has regained its red colour, and the tint in this area is a more dusky red than in that of fluxion; sometimes small red dots may be noticed in the pale patch formed by the pressure of the finger, indicating points at which some red corpuscles have escaped from the distended vessels. Lastly, close to the dead tissue is a dark red line unaltered by pressure, indicating the area of stasis and thrombosis, in which also many red corpuscles have escaped from the damaged vessels. From the vessels in the stage of retarded flow abundant exudation of blood-plasma and migration of the corpuscles take place. The wandering cells move in great numbers into the passive layer of tissue touching the dead part, and by their pressure destroy such remains of vitality as may be left; the original tissue softens and disintegrates, its place becomes occupied by closely-packed leucocytes; the leucocytes in contact with the irritating dead tissue in their turn disintegrate, and becoming granular and losing their adhesion, are separated from each other by the serous exudation from the neighbouring vessels, and thus pus is formed and the process of separation is completed. When this has

taken place a surface is left covered superficially by a uniform layer of closely packed cells derived from the white corpuscles which have migrated from the vessels. Such a surface is a simple ulcer. The dead tissue which acted as a foreign body being removed, if no further source of irritation be present, the surrounding tissues recover from their impaired vitality, the inflammation subsides, migration ceases, and the process of **repair** commences. This process will be described in the next chapter with repair in general. (*See Union by the Second Intention*).

Ulceration, as it occurs from the inoculation of a specific poison, as in the example of the soft chancre before given, differs in no respect from that just described, except that at no time is there a visible piece of dead tissue cast off, and that the irritant which causes the process is developed persistently in the discharges, and, unless it be in some way destroyed, may continue to maintain the destructive process almost indefinitely. It is evident that if the irritating virus developed in the sore is of sufficient intensity, it may cause death of the tissues before the process of absorption of the original structures and substitution of a mass of leucocytes for them has had time to be completed. It is under these circumstances that ulceration merges into spreading gangrene, the tissues no longer appearing to melt away in the liquid discharges, but remaining as a soft, partially disintegrated slough on the surface of the sore.

The process of formation of an ulcer in skin which has long suffered from chronic inflammation has been well described by Billroth. "Let us suppose," he says, "that we have a chronic inflammation of the skin of the leg, say on the anterior surface of its lower third. The skin is traversed by dilated vessels, hence it is redder than normal; it is swollen, partly from serous, partly from plastic infiltration: and it is sensitive to pressure. Wandering cells are infiltrated, especially in the superficial parts of the cutis: this renders the papillæ longer and more succulent: the development of the cells of the rete Malpighii also becomes more plentiful, and its superficial layers do not pass into the normal horny state: the connective tissue of the papillary layer is softer, and becomes partly gelatinous. Now, slight friction at any point suffices to remove the soft, thin, horny layer of the epidermis. This exposes the cell-layer of the rete Malpighii; new irritation is set up, and the result is a suppurating surface, whose upper layer consists of wandering cells, the lower of greatly degenerated and enlarged cutaneous papillæ. If at this stage the part were kept at perfect rest, and protected from further irritation, the epidermis would be gradually regenerated, and the still superficial ulcer would cicatrise. But usually the slight superficial wound is too little noticed, it is exposed to new irritations of various kinds: there are suppuration and molecular destruction of the exposed inflamed tissue, then of the papillæ, and the result is a loss of substance which gradually grows deeper and wider: the ulcer is fully formed."

Causes.—*The conditions essential to ulceration are:*— 1. An irritant acting on a limited portion of the living tissues with sufficient intensity to cause the stage of retarded flow in the vessels with abundant migration of leucocytes, culminating in stasis and death in the parts most directly acted on. 2. A persistent action of the irritant for a sufficient time.

We have before seen, in the Chapter on Inflammation and Suppuration, that the effect produced on a living tissue by an irritant depends partly on the intensity of the irritant itself, and partly on the power of resistance of the

tissues, or, in other words, their degree of vitality. Consequently, the causes of ulceration, like those of inflammation in general, are divided into **Predisposing**, or those which render the tissues liable to suffer severely from injurious influences by impairing their vitality; and **Exciting**, or, in other words, the injurious influences themselves.

Predisposing Causes.—Everything that acts as a predisposing cause of inflammation is also a predisposing cause of ulceration (see p. 172), and the following may be mentioned as amongst the most important. They are chiefly conditions that interfere in some way with the nutrition of a part. A feeble circulation, such as often exists in the lower limbs, in the alæ of the nose, and in newly formed or recently cicatrised tissues, predisposes to the formation of ulcers. As age advances, nutrition becomes impaired and the circulation less active, and slight causes suffice to lead to disintegration of the structure of a part. Hence we commonly see ulcers of the legs in elderly people, more particularly amongst the poorer classes, arising from slight irritation or pressure. Parts cut off from connection with a healthy nerve-centre ulcerate readily, as the nates in paraplegia.

Tissues that have been passively congested for a long time are apt to inflame under the influence of some trifling exciting cause, and to run rapidly into ulceration. This usually commences in the centre of the part, where the nutrition is lowest: here a small sore forms, which exudes thin unhealthy pus, and rapidly extends. So long as the sore is inflamed, it continues to spread, and repair cannot take place. In some cases in which, from the above causes, the vitality has been greatly lowered, the exciting cause which is sufficient to give rise to ulceration may be so slight as to escape detection. This is especially marked in scrofula, scurvy, and syphilis. In many forms of tuberculous and syphilitic ulceration the process resembles in many respects that of malignant ulceration—the chronic inflammatory products first forming a solid mass of very slow growth, almost like a tumour, which ultimately degenerates and softens in the centre, and is discharged superficially, leaving a raw surface, which slowly spreads by ulceration. These form a connecting link between simple inflammatory ulceration and ulceration from malignant growths.

Exciting Causes.—The direct exciting causes of ulceration act chiefly on the skin and mucous membranes, and are very various in character:—

1. The most rapidly spreading forms of ulceration arise from specific infective poisons, as in phagedænic ulcers, hospital gangrene, soft chancre, the sore throat of scarlet fever, and in many syphilitic ulcerations. Most of these, at the same time, cause acute inflammation, extending to some distance beyond the area in which destruction of the tissues is visibly taking place. In such cases the action of the irritant may be so acute, and the destruction of the tissues so rapid, that the migratory cells may not have completely displaced the original structures before disintegration occurs. Microscopic shreds of the dead tissues are then to be found in the pus, which contains fewer genuine pus-cells and assumes often the form of a dirty brownish fluid, discoloured by the broken-up red corpuscles from the disintegrating layer of tissue. When the irritant is more potent still, and penetrates into the surrounding parts, destroying them rapidly before any extensive migration has had time to take place, layers of disorganised tissue constituting "sloughs" are formed, which completely cover the surface, and the discharge may be merely serous fluid, scarcely

turbid with cells. The whole process thus merges into gangrene. No sharp line can be drawn between spreading gangrenous inflammation and ulceration, and we call the intermediate conditions by such names as sloughing, gangrenous or phagedenic ulceration.

2. In parts which have long suffered from chronic inflammation, slight mechanical and chemical causes give rise to ulceration.

3. Ulceration sometimes commences in the crypts, or follicles, which open on mucous surfaces, as a consequence of catarrhal inflammation, with accumulation of secretion within their cavities. It leads to the formation of circular depressed ulcers.

4. In some general diseases, accompanied by the formation of vesicles or pustules on the cutaneous surface, ulcers may be left when they burst, as in small-pox, pemphigus, syphilitic rupia, and occasionally in chicken-pox.

5. Any injurious influence, whether chemical or mechanical, which causes the death of a part, necessitates the occurrence of ulceration for the separation of the dead tissue, and the sore so left is an ulcer. Long-continued pressure is a common cause.

6. In some specific cases, as before stated, ulceration is preceded by the formation of a morbid growth, as a syphilitic gumma, tubercle, or a malignant tumour.

Situation.—Ulcers may be situated upon any part of the cutaneous surface as the result of loss of substance from wound or other injury. Syphilitic or strumous ulcers may appear on almost any part either of the skin or the mucous membranes, but they most frequently occur in particular situations, as on the penis, lips, tongue, or rectum. Of all forms, however, perhaps the most common with which we have to deal, is the simple ulcer of the leg, so frequently seen in hospital out-patient rooms. The lower half of the leg is the usual seat of these simple ulcers, the skin of that part being much exposed to mechanical violence, and very prone to congestion from position, from varicose veins, and from its great distance from the centre of circulation. In advanced life, moreover, degenerative changes in the arteries of the leg obstructing the flow of blood are very common. Ulcers that form here are slow in healing, and very likely to recur, because the conditions that led to their formation may still exist: also there is often but a very thin layer of subcutaneous fat between the skin and the tibia, and, consequently, there is a great tendency for the under surface of the scar to adhere to the bone.

GENERAL TREATMENT OF ULCERATION.—In the **Local Treatment** of ulceration, the Surgeon must be guided by the special conditions presented by the ulcer, as presently described; but there are some points which demand attention in all cases. 1. Every source of irritation which could cause inflammation, or maintain it if present, must be carefully removed: for while inflammation is present no proper reparative process can go on. Thus, if the ulceration be due to the presence of a specific poison, as in the case of a soft chancre, this must be destroyed by antiseptic or caustic applications. In simple sores the surface must be preserved from friction, the part must be kept at rest, and the decomposition of the discharges must be prevented by proper applications. 2. The circulation must be maintained in a normal state, both congestion and local anemia being guarded against, as, without a normal supply and a sufficiently rapid change of blood, the growth of the reparative tissue cannot take place. Constriction must therefore be avoided, and the

part must be placed in such a position as will favour the return of blood from it. 3. Proper local applications adapted to the nature of the case must be employed, conjoined with uniform pressure, to support the dilated and weakened vessels of the part.

The **Constitutional Treatment** must be carefully attended to. Unless this be done, the best regulated local measures may be employed in vain. Attention to the digestive organs, and improvement of the constitution, if it be strumous or syphilitic, will do more in these cases than any other means can accomplish. The nutrition of the patient requires due care.

VARIOUS FORMS OF ULCERS.

When ulcers occur in the skin, as the result of non-specific disease, they may be arranged under the following heads: the Healthy; the Weak; the Irritable; the Inflamed; the Phagedenic or Sloughing; and the Varicose. Besides these varieties, each of which is marked by distinct characteristics, various other forms of ulceration depending on specific causes, as the Syphilitic, Tuberculous, Lupoid, Cancerous, &c., are met with; all of which will be treated of in their special chapters.

The varieties presented by ulcers are by no means dependent on local conditions merely, but are in a great measure owing to constitutional causes. Indeed, the aspect of the ulcer, and the character of its granulations and of its discharge, are excellent indications of the general condition of the patient as well as of the local disease.

In studying an ulcer clinically, we have to pay attention to the following points: 1. The surrounding skin. 2. The edges of the sore. 3. The surface of the sore. 4. The base of the sore. 5. The nature of the discharge; and 6. Pain and tenderness.

The Healthy Granulating Sore.—The *surrounding skin* is free from oedema; there is no change in it beyond slight hyperæmia close to the margin of the sore: the *edges* are regular in outline, shelve gradually down to the surface of the sore, and are marked by three zones of colour, an outer opaque white, a middle opalescent blue, and an inner dark red, as described in the chapter on Repair. The *surface* is slightly depressed, and thickly studded with florid red granulations, firm in structure and uniform in size, each being about as large as half a mustard seed. The *base* of the sore is soft, and not adherent to deep-seated structures, as bones or fasciæ. The *discharge* will, under ordinary circumstances, be thick, creamy, laudable pus; but by carefully excluding every source of irritation, it may be made to assume a more or less serous character. There is no *pain or tenderness*. It is the object of our treatment in all cases to bring the other forms of ulcer into this condition.

Treatment.—In the management of the healthy granulating sore, the treatment should be as simple as possible; the application of some simple dressing and the pressure of a bandage usually enable it to cicatrise. Perhaps the best of all antiseptics for this purpose is a concentrated solution of boric acid. A piece of lint exactly the size of the sore is moistened with the solution and put on the surface; over this must be placed a piece of oiled silk or thin gutta-percha tissue, overlapping the lint in all directions for about

one-eighth of an inch. Uniform pressure is secured with a bandage, and the dressing must be changed at least daily.

Boric acid lint, wetted with the lotion, may be applied to foul sores in the same way; when the sore becomes perfectly healthy and free from decomposition, its surface may be protected from the direct action of the antiseptic by covering it with the green oiled silk dipped in the lotion before being applied; over this the boric acid lint may be placed either wet or dry to absorb the discharge. Another excellent application to a healthy ulcer is the boric acid ointment spread on thin muslin, the whole being dipped in the lotion to make it apply itself smoothly before being put on the sore: over this may be placed a pad of salicylic wool to catch the discharge, the whole being secured by a bandage.

Carbolic acid solution (2 per cent.) has the great disadvantage of being irritating when first applied, and, as the acid becomes rapidly volatilised, it soon becomes inefficient.

If, from any reason, it may be considered desirable to dress the sore less frequently, a more lasting dressing may be applied thus: wash the sore and the surrounding skin well with a solution of carbolic acid (1 in 40): put on a piece of the protective green oiled silk, completely covering the raw surface, and then apply the carbolic gauze dressing, as described in the Treatment of Wounds (Chap. IX.). If economy be of consequence, one layer of gauze may be applied to keep the leg clean, over this may be placed a thick pad of carded oakum, and the whole covered by a common bandage. If the carbolic acid gauze irritate the skin, its place may be taken by eucalyptus gauze, or the part may be enveloped in a sheet of iodoform wool, salicylic wool or some absorbent mercurial dressing. By any of these modes of treatment it is possible to get the ulcer into so clean a state, and so far to diminish its discharge, that it shall not be necessary to change the dressing more than once a week. It will be observed that the object of these modes of dressing is to protect the sore from every possible source of irritation, including not only the products of putrefaction, but also the antiseptic agent which is employed to prevent decomposition. Sometimes, however, as has already been stated, the healing process is retarded or arrested in consequence of the extent of the ulcer. In such cases, the transplantation of cuticle will, by affording centres of cicatrisation, expedite the cure.

Whatever mode of treatment be adopted, if the ulcer be on the leg, rest in bed with elevation of the limb has more influence than any other condition in hastening the cure.

Skin-Grafting.—The fact that freshly separated parts if immediately re-applied to a raw surface may contract adhesions to it and retain their vitality was demonstrated long ago. Hunter showed that teeth could be successfully transplanted, and that the spurs of a young cock could be "made to grow on his comb;" Walther that the button of bone removed by a trephine, if reinserted, will contract fresh adhesions, and many Surgeons had recorded cases of adhesion of freshly separated portions of the nose or chin. But little practical use was made of these observations till Reverdin suggested in 1869 that transplanted cuticle might be used to hasten the cicatrisation of granulating surfaces.

The growth of new epithelium over the surface of a sore takes place from the epithelial cells at its margin: and Reverdin showed that by planting small

islets of freshly separated cuticle on the granulating surface, each can be made to form a centre for the development of new epithelium, which, spreading in all directions, coalesces with that growing from the surrounding skin, and thus rapidly covers the sore. The covering of the surface with epithelium is, however, only a part of cicatrisation, the contraction of the granulation-tissue and its development into fibrous tissue forming an equally essential process. The hopes that were entertained at one time, that by the grafting of cuticle the contraction of the scar, which causes such extensive deformity in the case of large burna, could be prevented, have been but imperfectly realised. The process of grafting, in fact, in many cases amounts to little more than dressing the sore with cuticle, if such an expression may be allowed, the new epithelium cells growing over the surface long before the development of the fibrous tissue of the scar has made any appreciable progress. In such cases the cicatrix formed is very weak and apt to break down—much more readily than the scar produced by the natural process of healing. Moreover, even after successful grafting, much contraction frequently takes place as the granulation-tissue becomes completely developed into fibrous tissue. Still, however, transplantation of cuticle is of great use in promoting the healing of large sores; and probably, although it does not prevent the subsequent contraction, it does in some cases lessen its amount.

The process of transplantation of cuticle is as follows: If the sore be not septic, it should be dressed every four hours with boric lint moistened with a concentrated solution of boric acid. In about forty-eight hours the sore will be free from septic matter. A piece of skin on some sound part of the body—the outside of the arm, for instance—about the size of an oat, is pinched up with a pair of forceps, and snipped off with curved scissors. The whole thickness of the skin need not be separated, but merely the cuticle down to and including the papillary layer of the true skin, so as just to draw blood. The operation, when properly performed, is almost painless. The little patch of cuticle is now placed, with the raw side downwards, on the surface of the ulcer, care being taken not to injure the granulations in so doing. It is better to apply several small grafts of skin than one large one. Each graft is now covered with a small piece of "green protective," and the ulcer is dressed with a thin layer of boric acid ointment spread on muslin, and dipped in boric acid lotion before being applied. Over this again must be placed a thick layer of iodoform or salicylic wool. The dressing may then be left undisturbed for four days.

It frequently happens that by the third or fourth day the graft has entirely disappeared, but becomes again recognisable a few days after. This is due to the desquamation of the opaque corneous layer of the transplanted cuticle leaving only the thin transparent Malpighian layer behind; the reappearance of the graft takes place as soon as sufficient new epithelium has grown to be again opaque.

For the success of this little operation, it is necessary that the granulating surface, on to which the transplantation is made, should be a healthy one, and that the process of cicatrisation should have commenced at its edges.

When many grafts are required, and especially if the patient be old or nervous, it may be convenient to obtain some from another person. It must not be forgotten that syphilis may be communicated in this way if the grafts are taken from a person suffering from that disease in its active stage. Deubel

records a case in which, to repair great loss of skin from gangrenous erysipelas in an old man, grafts were taken from his son. The treatment was apparently successful, and complete healing took place, but soon afterwards spreading ulcers formed, and the whole scar was destroyed. Roseola appeared ten weeks after the first graft was applied, and was followed by mucous tubercles in the mouth. The son was found to have condylomata about the anus, and had suffered eighteen months before from a hard chancre.

The method of skin-grafting recommended by Thiersch is now largely employed in the treatment of granulating surfaces. It is performed as follows: The granulations are scraped away to the firm underlying tissue, and the hæmorrhage arrested by sponge-pressure. The grafts are made by cutting the thinnest possible slices with a broad, flat razor from some part of the patient's body, preferably the outer surface of the forearm or the front of the thigh. Strips measuring four inches in length and three-quarters of an inch in breadth can thus be obtained, and will live if applied to the raw surface. The grafts should be made slightly to overlap each other as well as the edges of the raw surface, and the latter, if of only moderate size, can be thus completely covered. The whole is covered with protective oiled silk, and a gauze dressing applied. The surface from which the grafts are removed is rapidly covered with epithelium, as in the healing of a burn of the third degree (see p. 393). The healing produced by Thiersch's method is permanent, because the weak granulations are scraped away, and, for the same reason, the contraction of the cicatrix is much diminished.

Operation wounds, which it is found impossible to close by suturing, can be treated in the same way; thus, Watson Cheyne has successfully used the method after excision of the breast in cases where free removal of skin was necessary, the skin grafts being placed on the surface of the pectoral muscle.

True Skin-Grafting, that is to say, the transplantation of portions of the complete thickness of the skin, has frequently been performed for the restoration of portions of lost skin from the face. The details of this operation as it is performed for ectropion will be found in the chapter on Plastic Surgery (chap. LVII). It is essential that every vestige of subcutaneous fat should be removed from the under surface of the cutis, otherwise it will almost certainly fail to unite in its new situation. Skin transplanted in this way will adhere either to a fresh raw surface or to a granulating sore, but much more readily to the former. R. C. Lucas has shown that the skin of the prepuce, being devoid of fat, makes excellent grafts for a granulating sore. In hospital practice the opportunities of obtaining the necessary material are very frequent, and may often be taken advantage of in the treatment of the large granulating sores left after burns.

Weak Ulcer.—This most commonly occurs from emollient applications having been continued too long, and especially from the application of poultices. It differs from the healthy sore in that the *edges* want the healing line, and the *surface* is raised above the surrounding skin and covered by flabby semi-transparent granulations sometimes rising in exuberant, gelatinous masses above the edges of the sore. These granulations have a feeble vitality, and *heal slowly*. Popularly they are spoken of as "proud flesh."

The *Treatment* consists in keeping the part elevated and carefully bandaged, and applying an astringent dressing to the sore, such as the "red wash," or

a weak solution of the sulphate of copper. Red wash is prepared according to the following formula: Sulphate of zinc, sixteen grains; compound tincture of lavender, two drachms; water, eight ounces. It will be found a most useful application. The granulations may also be touched from time to time with nitrate of silver. Creolin will be found a useful application in some cases (p. 210).

Indolent or Callous Ulcer.—This is always very chronic. It is situated usually on the outer side of the lower extremity, between the ankle and the calf, and it most frequently occurs in men about the middle period of life. The *surrounding skin* is congested, and usually presents the appearances indicative of long-continued passive hyperæmia, being frequently darkly pigmented and always indurated. The induration affects the subcutaneous areolar tissue, which is solid and brawny, and firmly fixed to the subjacent fascia, or in some cases even to the bone. There is a total loss of elasticity, both in the skin and in the subcutaneous tissue. The epidermis is often scaly and desquamates in large flakes. In many cases the cause of the mischief will be found to be varicose veins, which have given rise to chronic congestion of the skin. The *edges* of the sore are often irregular; they are hard, elevated considerably above the surface of the sore, and sink abruptly into it. The *surface* is either smooth and covered with a yellowish layer, or irregular and formed in parts of pale, feeble granulations. The *base* is hard, and firmly fixed to the subjacent tissue or bone. The *discharge* is thin and serous. There is no pain attending this ulcer, and its surface, which often attains a very large size, may usually be touched without the patient feeling it.

It is always slow to heal, for contraction forms an essential part of the healing of a sore, and the rigidity of the surrounding tissue renders this almost impossible.

Treatment.—The principle of treatment here is to soften the surrounding tissues and depress the edges of the sore by promoting absorption of chronic inflammatory products with which they are infiltrated. When this is accomplished, contraction becomes possible, and healing will progress. This is best effected by pressure.

A very efficient plan of treatment is as follows: The surface of the ulcer may first be rubbed with nitrate of silver, after which three or four layers of boric acid lint dipped in hot solution of boric acid and covered with oiled silk and cotton-wool should be applied and changed every four hours. After forty-eight hours of this treatment the sore will be perfectly clean, and may then be strapped on the plan recommended by Baynton. The best plaster for this purpose is the *emplastrum saponis*, to which some of the *emplastrum resine* is added to make it sufficiently adhesive; this, spread upon calico, should be cut into strips sixteen or eighteen inches in length, and about an inch and a half in width; the strips are dipped in hot carbolic or boric acid solution and applied wet; the centre of the strip should then be laid smoothly on the side of the limb opposite to the sore, and the ends, being brought forward, are to be crossed obliquely over it. Strip after strip must be applied in this way, until the limb is covered for a distance of a couple of inches above and below the ulcer. If the sore be near the ankle, this joint should be included in the strapping. Each strip of plaster should be applied with an equal degree of pressure, which may often be considerable, and it should cover at least one-third of the preceding strip.

the cells into spindle-shaped "fibroblasts," which are arranged in lines chiefly parallel to the vessels. Fibrillation now occurs between the cells, many of which disappear, until only a few flattened ones remain amongst the bundles of fibres. At the same time, a gradual obliteration of the abundant vessels of the granulation-tissue occurs, and thus finally the surfaces of the original wound are firmly united by a thin layer of dense cicatricial fibrous tissue.

Scar-tissue differs from healthy areolar tissue in being more dense, in containing no lymphatics, and in the absence of yellow elastic fibres. It is this that gives a scar its rigidity and want of elasticity. Very old scars are said to become gradually more closely like normal fibrous tissue, and even to develop yellow elastic tissue.

Two chief views are held regarding the origin of those cells of the granulation-tissue from which the new connective-tissue cells are formed: 1st. That they are developed directly from the migrating leucocytes. 2nd. That they

Fig. 18. A cicatrix, three weeks old after union by the first intention; *nc*, normal epithelium; *ec*, epidermis covering the scar; *a*, young fibrous tissue containing elongated cells parallel to the vessels; *v*, a vein; *gl*, a sweat gland; *f*, fat. The tissues on each side of the scar contain numerous leucocytes.

are formed by multiplication of the original cells of the part, which commence to divide as soon as the temporary damage done them by the injury has ceased. The difficulties in the way of the observer are great: the migration of leucocytes more or less obscures the original cells of the part, and a connective-tissue cell in process of multiplication assumes the form of a group of small cells closely resembling leucocytes.

Senffleben has shown that in the cornea a loss of substance may be obtained without inflammation, and that, under these circumstances, the corneal corpuscles may be seen to take a direct part in the process of repair. Ziegler has shown that connective-tissue can develop in a small capillary glass chamber placed beneath the skin of a dog, and he believed that the tissue was formed from migrated leucocytes which were found filling the chamber soon after its insertion. Sherrington and Ballance have experimented on the same lines as Ziegler. With full antiseptic precautions, they placed small glass chambers in the peritoneal cavity or subcutaneous tissue of rabbits and guinea-pigs, and examined the contents microscopically after periods

surrounding skin is eczematous. A paste, which differs slightly from the original formula, is prepared by heating together gelatine, 15 parts, glycerine, 30 parts, oxide of zinc, 10 parts, and water, 45 parts.

This paste, melted by heat, is thickly painted over the affected portion of the limb, and covered by a firmly applied gauze bandage, which Unna suggests should be double-headed, and crossed backwards and forwards round the part. A fresh layer of the paste may be painted over each layer of the bandage. The dressing can be left undisturbed for several days. Excellent results have followed this mode of treatment.

Another mode of treating chronic ulcers is that which was recommended by Serme, consisting in the application of a blister to the indurated edges and the surface of the sore, after which some simple dressing is used. This is often efficient, but if the sore be of any considerable size, it is possible that the patient may absorb sufficient cantharidin to cause symptoms of poisoning.

If the edges of the ulcer are so indurated that the contraction necessary for healing is impossible, Volkmann recommends that an incision should be made through the indurated tissues completely around the ulcer, and at a short distance from its margin.

Farther, it must be mentioned that Thiersch's method of skin-grafting (p. 278) has been successfully applied to the treatment of callous ulcers. In cases of extensive intractable ulcers, which resist every method of treatment, amputation is occasionally required.

Irritable Ulcer.—This is met with mostly after the middle period of life. It is usually of small size, and situated behind one or other malleoles. It is frequently a consequence of varicose veins. The *surrounding skin* is usually purple, slightly indurated and sometimes pigmented; the *edges* are slightly raised, very irregular in outline, and present no signs of healing. The *surface* is but slightly below the level of the skin; it is either dark purplish-red in colour or covered with a thin slough. The *base* is but slightly indurated. The *discharge* is scanty and thin. The *pain* is the principal characteristic; it is exceedingly great, and usually worse at night, thus preventing sleep and seriously disturbing the general health. In fact, such an ulcer, if unrelieved, may bring the patient into so exhausted a condition that death may occur from some apparently slight ailment, such as an attack of bronchitis. Hilton pointed out that if the surface of the sore be carefully touched all over with the point of a probe, one or more spots will be found most acutely tender. This is due to the exposure of a nerve-ending on the surface of the

In the *Treatment* of this ulcer, sedatives at bedtime are often necessary to procure rest. If opium be used, the constipation must be relieved by saline purgatives in the morning. The local treatment which I have found most successful, is to brush the surface of the sore and the surrounding parts from time to time with a strong solution of nitrate of silver (gr. x. to ʒj.), and then to keep sedative remedies, such as lead and opium lotions, applied to it. If this does not succeed, the surface of the sore may be rubbed with solid nitrate of silver until a distinct slough is formed. The treatment may be rendered painless by the previous application of a 10 per cent. solution of cocaine; the smarting, if there be any, soon ceases, and the patient will often enjoy after it the first good night's rest he has had for months. Hilton

the ulcer heal, it constantly breaks open again; or hæmorrhage may occur from a ruptured vein on its surface. Other means, which will be described in a future chapter, must then be taken for the permanent occlusion of the varicose vessels.

Ulcers on Mucous Membranes.—Various forms of ulcer occur upon mucous membranes, especially those of the throat, rectum, and genital organs. As these, however, are commonly specific, they will be described hereafter.

Ulcers of mucous membranes, when not of a specific character, present the general appearances characteristic of the cutaneous healthy, inflamed or weak varieties; and require the topical applications which have been described as suited to these conditions; though generally they will demand the free employment of caustics, or astringents, especially of the nitrate of silver.

CHAPTER VII.

THE PROCESS OF REPAIR.

HAVING, in the preceding chapters, described certain pathological conditions in which interference with normal nutrition and destruction of tissue form the most prominent features, we have now to give a summary of the processes by which repair takes place.

It will be most convenient to consider repair, first, as it is seen in the union of a simple wound, the surfaces of which can be brought accurately in contact with each other : and secondly, as it takes place in wounds in which the loss of substance renders this impossible, or in which the injury is such that an adherent portion of dead tissue must be cast off before any repair can take place.

Five different modes of repair of incised wounds have been described : 1. **Immediate union** or direct growing together of the opposed surfaces. 2. **Union by primary adhesion**, through the medium of a coagulable exudation from the opposed surfaces. 3. **Scabbing**, in which one of the above processes occurs beneath a scab formed of the dried discharges. 4. **By granulation**, in which granulation-tissue springs up from the bottom and sides of the wound, and eventually becomes covered by an epithelial layer ; and 5. **By secondary adhesion**, in which two granulating surfaces, being placed in contact, grow together. The first two of these methods of repair are included under the term "union by the first intention," and are confined to incised and punctured wounds. The third is in reality merely an accidental condition attending union by the first intention. The last two may occur in closed wounds if union by first intention fail, and are the only means by which contused and lacerated wounds, with some rare exceptions, have been known to heal.

1. **Immediate Union.**—The direct growing together of opposite surfaces, "without any intervening substance, such as blood or lymph," was first described by James Macartney, of Dublin, in 1838. He was led to the opinion that such a process occurred by the observation of cases in which all the coarser signs of inflammation, redness, swelling, heat, and pain, with exudation, were wanting. John Hunter had believed that the bond of union in such cases was the extravasated blood. He thus described the process as he believed it to occur : "The mouths of the vessels are soon shut, either by coagulation, or their own power of contraction," "and if there should be any superficial extravasated blood, we know that it will be afterwards absorbed. The blood being alive, this uniting medium becomes immediately a part of ourselves, and the parts not being offended by it, no irritation is produced. The red particles are absorbed, and nothing but the coagulating lymph is retained, which, being the true living bond of union, afterwards becomes vascular."

The means of observation in the time of John Hunter were inferior to those of Macartney, yet there seems little doubt that his description, erroneous as it is, contains far more truth than that of the later observer. During the last twenty or thirty years the means of studying such processes have been greatly improved; and there can now be no doubt that such a mode of union as that described by Macartney never takes place. It is impossible to make a wound in any vascular part without damaging sufficiently the tissues to cause a coagulable exudation to take place, which, mixed with wandering cells, forms the first bond of union between the opposed surfaces. The quantity of this exudation may, however, be so small that it can be recognised only in microscopic preparations, cut, stained, and mounted, according to the modern methods; and it is not surprising, therefore, that it escaped the notice of former pathologists.

2. Union by primary adhesion (Paget), **primary union**, **union by adhesive inflammation** (Hunter), or, as it is more commonly called, **Union by the First Intention**, is that form of union which occurs without the formation of pus, and in which the accompanying inflammation is purely traumatic, being strictly limited to the tissues directly injured in the production of the wound. It is the form of union which the Surgeon aims at obtaining in all wounds unaccompanied by extensive loss of substance, or by such a degree of injury of the surface as to cause sloughing.

In order that primary union may take place, the following *conditions* are necessary: 1. That the wound be not contused or lacerated to such a degree as to cause visible sloughing of the surfaces. 2. That the interposition of any foreign bodies be carefully guarded against. 3. That the wound be closed, and its sides brought into accurate apposition. 4. That the surfaces after being brought together be kept at perfect rest. 5. That no cause of inflammation be introduced which shall tend to prolong the process beyond the period necessary for the effusion of healthy plastic exudation, or to make it spread beyond the area actually injured by the knife.

In studying union by first intention, it is essential to bear in mind the condition of the surface of a clean incised wound immediately after its infliction. The mechanical violence inflicted on the tissues by the instrument by which the wound was made, the exposure to cold air, and in the present day in many cases the application of some irritating chemical antiseptic, have all combined to damage the exposed tissues, and to lower their vitality to a degree sufficient to give rise to the process of inflammation. Here and there in individual cells or microscopic layers of tissue the damage is sufficient to cause actual death. In the whole of the immediate surface of the wound the vitality is lowered to a degree sufficient to cause stasis; immediately beyond this we find retarded flow with exudation of liquor sanguinis and migration of the white corpuscles, and beyond this again is an area of simple vascular dilatation—the degree of damage necessarily diminishing as we recede from the parts directly touched by the cutting instrument. The thickness of the layer of tissue thus injured must necessarily vary with the sharpness of the instrument with which the wound was made, the original vitality of the tissues, the amount of violence done in cleaning the wound, the duration of exposure to cold air, and the nature of any chemical antiseptic that may be applied to it; but in most cases of cleanly cut wounds, it is in all probability merely microscopic. This condition of lowered vitality is merely temporary; and, if no further cause of damage

be introduced, it will pass off in from twelve to twenty-four hours, when all the phenomena of inflammation which occur as a consequence of it will subside.

This being the condition of the surfaces of the wound, the early phenomena of union by first intention are readily explained by the application of the description of the process of inflammation already given. Hæmorrhage is first arrested. In the larger vessels this is effected by artificial means to be discussed hereafter, but in the smaller it occurs spontaneously. The mechanical stimulation caused by the cutting instrument causes a contraction of the smaller arteries extending some little distance from the surface of the wound, and amounting to complete or almost complete closure, and thus the rapidity of the capillary circulation supplied by them is retarded and its force diminished. Such blood as finds its way into the wounded capillaries when it reaches the damaged area shows the phenomena of stasis. The red corpuscles adhere to each other and to the wall of the vessel, and plug its lumen, and at the most damaged part where the vessel is divided the condition passes on to definite coagulation, and a small adherent clot is formed, which closes the open mouth of the capillary. The contraction of the arteries is merely temporary, and soon passes off, giving place to dilatation; but by the time this takes place, the clots in the divided capillaries are sufficiently firm and adherent to prevent a recurrence of the hæmorrhage. The fulness of the vessels resulting from the arterial relaxation is readily observable, and is indicated by the blush of redness, with slight swelling, always seen in the edges of a wound a short time after its infliction. This redness is not limited to the area actually injured by the knife, but extends to some distance, often one inch or more from the edge of the wound. The causes of this extensive blush of redness are, first, the stimulation of the sensory nerves consequent upon the wound, which, as we have before seen, causes vascular dilatation in the area supplied by the nerves acted on; and, secondly, the mechanical obstruction to the circulation caused by the obliteration of the vessels divided in the wound. The blood-pressure being thus increased, while at the same time the vitality of the walls of the vessels has been lowered or suspended in the injured area, abundant effusion of coagulable exudation, with escape of a greater or less number of red corpuscles and rapid migration of the white, sets in; and the exudation, finding a ready way by the open lymph spaces, pours out on the surface of the wound. Here it coagulates; the fibrin entangling innumerable white corpuscles in its meshes, mixed with a variable number of red, remains adherent to the surface, while the serum, darkly stained with red corpuscles, drains away. It is seldom in the present day that an opportunity is obtained of watching the naked-eye appearances of this process, as wounds are almost invariably closed as soon as possible after their infliction; but formerly many Surgeons left wounds open, to become "glazed," as it was called, before bringing them together. In an amputation wound treated in this way the process of exudation can be watched; drops of reddish serum accumulate here and there on the surfaces of the flaps, like beads of perspiration in profuse sweating; these by coalescence with others, and by gradual increase, reach a certain size, and then trickle off the surface of the exposed wound, like drops of rain down a window. After the process has lasted an hour or two, the surface of the flap begins to assume a glazed appearance, the "glaze" being formed of the coagulated fibrin mixed with corpuscles as above described. This material, to which in the present day the term "*plastic*"

exudation" is perhaps most conveniently applied, is spoken of also as "*coagulable lymph*," "*inflammatory lymph*," or "*lymph*." After the process has continued for some time, the serum, which was at first almost as red as pure blood, becomes almost colourless, and diminishes greatly in quantity. The two flaps, being now covered by the adhesive plastic exudation or lymph, adhere to each other readily with a certain degree of firmness if brought together, and thus a temporary union is obtained, which provides for the perfect rest and apposition necessary for the permanent growing-together of the opposed surfaces. The cessation of the exudation occurs as soon as the damaged vessels recover their normal state. The plastic exudation, just like a blood clot, assumes gelatinous form as the serum drains completely away from it. The excessive cellular exudate, however, which has been killed by the injury, remains in the wound, and is a source of irritation, of which has been discussed in the preceding chapter. The process of temporary union should be maintained for at least a week, the time varying with the extent of the damage done to the tissues in its production. The wound surface should be washed over with a solution of carbolic acid (1 in 20) or chloride of zinc (1 in 20) at the end of twenty-four hours, and the dressing removed at the end of twenty-four hours, in which it is impossible to obtain a permanent union. The discharge will continue to escape from the wound, and a union must necessarily occur in the same manner as in the case of an impermeable epithelial

... of removed at ... presents ... they have not ... disended ... small clots. ... increasing in number ... the part show no ... combination glueing ... leucocytes; ... concealed by ... small patches of ... with ... of the wound

... which ... similar ones ... punches, ... grow out ... form loops. ... the same course ... completed. ... of the vessel; they ... by what means the ... and unite, but it is not ... of a branching cell. This process of

vascularisation commences as soon as the inflammation ceases. Wywodzoff found distinct links commencing to form in a wound in the tongue of a dog forty-eight hours after the infliction of the injury. Probably in a healthy wound the process is completed by the fifth or sixth day. When fully developed the new vessels are very abundant, much more so than in healthy connective-tissue. We now have, therefore, as the uniting medium, a mass of rounded cells, amongst which ramify innumerable thin-walled capillaries—in short, a thin layer of **granulation-tissue**. Granulation-tissue differs from

Fig. 2. Granulation-tissue. X 800. A Superficial layer just breaking down into pus; *a*, coagulated intercellular substance; *b*, pus-cells. B Growing layer of granulation-tissue; *f*, blood vessels imperfectly developed; *c*, granulation-cells; *e*, cells with nuclei dividing; *g*, homogeneous ground substance coagulated by the hardening fluid. C Deeper layers of granulation-tissue developing into fibrous tissue; *h*, blood vessel; *d*, granulation cells lengthening out into spindle cells; *g*, ground-substance commencing to fibrillate; *j*, rudimentary fibres.

“plastic exudation,” or “lymph,” in containing vessels, and in possessing homogeneous intercellular substance, instead of the coagulated fibrin which has now disappeared. The cells which compose it are in many cases somewhat larger than white corpuscles, and some may be met with of a branched form.

In a wound uniting by first intention, the repair of the divided epithelium takes place early by a growth of the cells of the Malpighian layer.

The rounded cells of the granulation-tissue now become gradually transformed into connective-tissue cells; the first change being the elongation of

the cells into spindle-shaped "fibroblasts," which are arranged in lines chiefly parallel to the vessels. Fibrillation now occurs between the cells, many of which disappear, until only a few flattened ones remain amongst the bundles of fibres. At the same time, a gradual obliteration of the abundant vessels of the granulation-tissue occurs, and thus finally the surfaces of the original wound are firmly united by a thin layer of dense cicatricial fibrous tissue.

Scar-tissue differs from healthy areolar tissue in being more dense, in containing no lymphatics, and in the absence of yellow elastic fibres. It is this that gives a scar its rigidity and want of elasticity. Very old scars are said to become gradually more closely like normal fibrous tissue, and even to develop yellow elastic tissue.

Two chief views are held regarding the origin of those cells of the granulation-tissue from which the new connective-tissue cells are formed: 1st. That they are developed directly from the migrating leucocytes. 2nd. That they

Fig. 10. A cicatrix, three weeks old after union by the first intention. *ne*, normal epithelium; *sc*, new epithelium covering the scar; *a*, young fibrous tissue containing elongated cells peculiar to the vessels; *v*, a vein; *g*, a sweat gland; *f*, fat. The tissues on each side of the scar contain masses of leucocytes.

are formed by multiplication of the original cells of the part, which commence to divide as soon as the temporary damage done them by the injury has ceased. The difficulties in the way of the observer are great; the migration of leucocytes more or less obscures the original cells of the part, and a connective-tissue cell in process of multiplication assumes the form of a group of small cells closely resembling leucocytes.

Senffleben has shown that in the cornea a loss of substance may be obtained without inflammation, and that, under these circumstances, the corneal corpuscles may be seen to take a direct part in the process of repair. Ziegler has shown that connective-tissue can develop in a small capillary glass chamber placed beneath the skin of a dog, and he believed that the tissue was formed from migrated leucocytes which were found filling the chamber soon after its insertion. Sherrington and Ballance have experimented in some lines as Ziegler. With full antiseptic precautions, they placed glass chambers in the peritoneal cavity or subcutaneous tissue of rabbits, guinea-pigs, and examined the contents microscopically after periods

varying from four hours to eighteen days. These observers concluded that the film of connective-tissue which formed in the chamber was derived, not from the leucocytes, but from larger "plasma cells," which were also present, and were presumably derived from the fixed tissue cells. The results of experiment, together with a study of the mode of repair of epithelium, may thus be said to support the view that the new tissue formed in the process of repair is derived from the original connective-tissue of the damaged parts. The exact mode of origin of the fibres of the scar-tissue is another disputed point: it is uncertain whether they are formed by a change in the protoplasm of the cells or by a process of fibrillation in the intercellular ground substance. Sherrington and Ballance were unable to satisfy themselves on this point, but inclined to the belief that the fibres were formed in an intercellular substance secreted by the cells.

The **time occupied in the process of repair** is not accurately defined. We have already seen that the formation of the "plastic exudation," or "lymph," commences immediately after the injury, and under favourable circumstances is finished by the end of the first twenty-four hours. According to Billroth, new vessels can be seen commencing to form within forty-eight hours, and by the end of a week a complete communication is established between the capillaries on each side of the wound. Early in the second week the cells have lengthened out, and the development of fibrous tissue has commenced: and by the end of the second week the superabundant vessels have been partly obliterated, and the new tissue has assumed a considerable degree of firmness. The final obliteration of the vessels in the cicatricial tissue is a slow process, lasting many months. Until this is completed the scar remains redder than the surrounding skin, though afterwards it becomes opaque and white.

It is evident that these changes can be seen on microscopic examination only in those wounds in which the surfaces have been separated from each other by an appreciable layer of plastic exudation or coagulated blood. When the apposition of the surfaces has been more perfect, the layer of uniting material may be so thin as to be scarcely recognisable, and four days after the infliction of the wound it may be almost impossible to detect any bond of union, the line of the incision being marked only by the presence of a few wandering cells and some traces of unabsorbed red corpuscles. That true union, however, in such a case has not definitely taken place at this time is shown by the care which is necessary, in preserving the specimen for microscopic examination, to prevent the surfaces from separating from each other.

We have thus traced the development of a scar, and shown that in its formation new blood-vessels, epithelium, and fibrous tissue are developed, and that these structures alone form the bond of union after division of the soft parts. In wounds of cartilage, muscle and central nervous tissue, no regeneration of the original tissues takes place, the scar being composed solely of fibrous tissue. Large vessels when completely divided are obliterated and converted into a fibrous cord as far as the nearest collateral branch. As we shall see hereafter, bone is repaired by bone, and under favourable circumstances large nerves are completely united by normal nerve-tissue. In large scars, however, the development of new nervous tissue is very imperfect, if it occurs at all. Little is known of the formation of lymphatics in old scars; but dissections show that they are wanting in granulation-tissue and young scars.

the cells into spindle-shaped "fibroblasts," which are arranged in lines chiefly parallel to the vessels. Fibrillation now occurs between the cells, many of which disappear, until only a few flattened ones remain amongst the bundles of fibres. At the same time, a gradual obliteration of the abundant vessels of the granulation-tissue occurs, and thus finally the surfaces of the original wound are firmly united by a thin layer of dense cicatricial fibrous tissue.

Scar-tissue differs from healthy areolar tissue in being more dense, in containing no lymphatics, and in the absence of yellow elastic fibres. It is this that gives a scar its rigidity and want of elasticity. Very old scars are said to become gradually more closely like normal fibrous tissue, and even to develop yellow elastic tissue.

Two chief views are held regarding the origin of those cells of the granulation-tissue from which the new connective-tissue cells are formed: 1st. That they are developed directly from the migrating leucocytes. 2nd. That they

Fig. 49.—A cicatrix three weeks old after union by the first intention: *ec*, normal epithelium; *e*, new epithelium covering the scar; *ec*, young fibrous tissue containing elongated cells parallel to the vessels; *v*, a vein; *g*, a sweat gland; *f*, fat. The trunks on each side of the scar contain numerous leucocytes.

are formed by multiplication of the original cells of the part, which commence to divide as soon as the temporary damage done them by the injury has ceased. The difficulties in the way of the observer are great: the migration of leucocytes more or less obscures the original cells of the part, and a connective-tissue cell in process of multiplication assumes the form of a group of small cells closely resembling leucocytes.

Saeflieden has shown that in the cornea a loss of substance may be obtained without inflammation, and that, under these circumstances, the corneal corpuscles may be seen to take a direct part in the process of repair. Ziegler has shown that connective-tissue can develop in a small capillary glass chamber placed beneath the skin of a dog, and he believed that the tissue was formed from migrated leucocytes which were found filling the chamber soon after its insertion. Sherrington and Ballance have experimented on the same lines as Ziegler. With full antiseptic precautions, they placed small glass chambers in the peritoneal cavity or subcutaneous tissue of rabbits and guinea-pigs, and examined the contents microscopically after periods

varying from four hours to eighteen days. These observers concluded that the film of connective-tissue which formed in the chamber was derived, not from the leucocytes, but from larger "plasma cells," which were also present, and were presumably derived from the fixed tissue cells. The results of experiment, together with a study of the mode of repair of epithelium, may thus be said to support the view that the new tissue formed in the process of repair is derived from the original connective-tissue of the damaged parts. The exact mode of origin of the fibres of the scar-tissue is another disputed point: it is uncertain whether they are formed by a change in the protoplasm of the cells or by a process of fibrillation in the intercellular ground substance. Sherrington and Ballance were unable to satisfy themselves on this point, but inclined to the belief that the fibres were formed in an intercellular substance secreted by the cells.

The **time occupied in the process of repair** is not accurately defined. We have already seen that the formation of the "plastic exudation," or "lymph," commences immediately after the injury, and under favourable circumstances is finished by the end of the first twenty-four hours. According to Billroth, new vessels can be seen commencing to form within forty-eight hours, and by the end of a week a complete communication is established between the capillaries on each side of the wound. Early in the second week the cells have lengthened out, and the development of fibrous tissue has commenced: and by the end of the second week the superabundant vessels have been partly obliterated, and the new tissue has assumed a considerable degree of firmness. The final obliteration of the vessels in the cicatricial tissue is a slow process, lasting many months. Until this is completed the scar remains redder than the surrounding skin, though afterwards it becomes opaque and white.

It is evident that these changes can be seen on microscopic examination only in those wounds in which the surfaces have been separated from each other by an appreciable layer of plastic exudation or coagulated blood. When the apposition of the surfaces has been more perfect, the layer of uniting material may be so thin as to be scarcely recognisable, and four days after the infliction of the wound it may be almost impossible to detect any bond of union, the line of the incision being marked only by the presence of a few wandering cells and some traces of unabsorbed red corpuscles. That true union, however, in such a case has not definitely taken place at this time is shown by the cure which is necessary, in preserving the specimen for microscopic examination, to prevent the surfaces from separating from each other.

We have thus traced the development of a scar, and shown that in its formation new blood-vessels, epithelium, and fibrous tissue are developed, and as a rule these structures alone form the bond of union after division of the soft parts. In wounds of cartilage, muscle and central nervous tissue, no regeneration of the original tissues takes place, the scar being composed solely of fibrous tissue. Large vessels when completely divided are obliterated and converted into a fibrous cord as far as the nearest collateral branch. As we shall see hereafter, bone is repaired by bone, and under favourable circumstances large nerves are completely united by normal nerve-tissue. In large scars, however, the development of new nervous tissue is very imperfect, if it occurs at all. Little is known of the formation of lymphatics in old scars; but injections show that they are wanting in granulation-tissue and young scars.

The process of union by first intention is disturbed by any cause which prolongs the inflammation, or makes it assume a spreading or infective character. Under these circumstances the transudation of liquor sanguinis and the migration of the white corpuscles will continue, and instead of the thin layer of dry firm plastic exudation, composed merely of living corpuscles entangled in the meshes of the coagulated fibrin, there will be a soft exudation, excessive in quantity, the more superficial layers of which will soften and break down into pus, a fluid layer thus being interposed between the surfaces of the wound, effectually preventing primary union.

Amongst the causes which lead to persistence of inflammation in a wound and consequent suppuration, the following may be mentioned as the most common :—

1. The nature of the injury ; a blunt or jagged weapon may so damage the tissues as to cause actual death of a layer of some thickness, which must be separated by a process of ulceration (see p. 272).

2. The tissues themselves may be feeble either from general or from local causes, and consequently possess a diminished power of resisting injury and rallying from its effects.

3. The raw surfaces may be constantly rubbed against each other if the wounded part be not kept at perfect rest, and the mechanical irritation from this cause is quite sufficient to maintain the process of inflammation.

4. If proper provision be not made for the escape of the serum that necessarily flows from the freshly wounded surface, the cavity of the wound becomes distended by it, and not only are the surfaces separated from each other, but they are exposed to the irritation of *tension*. While this is acting the inflammatory process cannot subside, but the exudation will continue and intensify the evil, the cavity of the wound coming to resemble that of an acute abscess. Tension from tight stitches causes a similar persistence of the inflammatory process.

5. If in such an undrained wound the causes of decomposition are present, putrefaction of the serous fluid speedily sets in, and the irritating products of decomposition, pent up as they are in contact with the raw surface at some degree of pressure, soak away into the lymph-spaces of the surrounding tissues, and thus cause a spreading inflammation which may extend to a considerable distance beyond the area actually injured by the instrument which inflicted the wound. The firm plastic exudation that is left uniting the surfaces of a well-drained wound being composed almost entirely of living cells is not liable to putrefaction, and any of the ordinary micro-organisms which may come in contact with it are powerless to produce any evil effect. It need hardly be pointed out that unless decomposable matter, either in the form of excessive blood-clot or pent-up serum, is present in the wound, no decomposition will take place.

6. The persistence of the inflammation may be due to the presence of a foreign body in the wound. A foreign body may act either from being itself irritating, mechanically or chemically, or from being porous in character, and thus absorbing serum, which afterwards decomposes. On the other hand, smooth non-absorbent bodies, such as metals, or soft absorbent substances, as unwaxed silk, under successful antiseptic treatment may become enclosed in a healing wound without causing the formation of pus.

7. Lastly, union by first intention is necessarily prevented by the inocula-

may be brought about by stimulation of the vagus. If that nerve be exposed in an animal, and stimulated by an electric current of moderate strength, the heart ceases to beat, and remains with all its cavities flaccid, as long as the stimulation is continued. If the current be very feeble, the action of the heart will recommence after a short interval, even if the passage of the current be continued: if very powerful, the inhibition will continue after the current has been removed. A current of sufficient strength may permanently arrest the heart's action. These effects may be brought about by reflex as well as by direct stimulation of the vagus. Thus, if a frog's foot be suddenly crushed, the heart ceases to beat for a moment, after which it acts for a short time more forcibly than before. This reflex inhibition is still more marked if the terminal branches of the vagus be directly stimulated. In dogs and rabbits sudden death has frequently been observed as a consequence of injury done to the larynx or trachea during an experiment.

These observations may be applied directly to man with the addition that in the human subject mental emotions frequently form the afferent impulse. Sudden death from shock has been recorded as the result of slight blows on the epigastrium, or of drinking ice-cold water, in both which cases a sudden stimulus is applied to the terminal branches of the pneumogastric nerve; and some sudden deaths under chloroform have been supposed to be due to reflex inhibition of the heart from the stimulation of the nerves of the trachea by too strong a dose of the anæsthetic.

2. Shock with General Exhaustion of the Nervous Centres, Collapse or Torpid Shock, is the form commonly met with after severe injuries and operations. No doubt at the moment of infliction of the injury cardiac inhibition takes place as above described, but this cannot explain all the phenomena of shock as usually met with in surgical practice. In fact, in extreme shock, the cardio-inhibitory centre seems to be exhausted, and the pulse, though feeble, is more rapid than natural.

The **symptoms** of shock vary according to the severity of the injury, the importance of the part injured, and the nervous susceptibility of the sufferer.

When the injury is not severe, does not implicate important parts, or occurs in an individual of strong nerve, the symptoms are slight and passing. But if the injury be very severe, if it affect a vital part, or if the sufferer be of excessive nervous susceptibility, the phenomena are much more marked.

In such cases, the sufferer becomes pale, cold, faint, and trembling; the pulse is small and fluttering; the respiration is shallow and feeble; there is great mental depression, the disturbed state of mind revealing itself in the countenance, and in feebleness or incoherence of speech and thought; the surface becomes covered with a cold sweat; the sphincters may be relaxed. In severe shock, the temperature commonly falls to about 97° Fahr. in the adult. In the young, the fall is less; in the aged, it is greater. I have several times found it below 95° Fahr. in the mouth and axilla, and Wugstaffe has met with cases in which recovery followed a fall of temperature amounting to four degrees. In fatal cases a fall of six degrees has been observed. These symptoms commonly set in immediately on the receipt of the injury. In some cases, however, there is an interval of time between the infliction of the injury and the appearance of the shock; this is more particularly the case in persons

there is always some source of irritation present which continues to act for a considerable time after the injury, and thus gives rise to a prolongation of the inflammatory process with the formation of pus. Thus, in a simple open wound with loss of substance, the raw surface is exposed to the influence of air, to the mechanical irritation of the dressings, and to the chemical irritation of antiseptic solutions in some cases and decomposing discharges in others. In poisoned wounds the specific virus with which they are infected maintains the inflammatory process. In cases of contused and lacerated wounds, or in burns and scalds, the dead tissue serves as a source of prolonged irritation until it is separated by ulceration and thrown off.

The process of union by the second intention is followed most easily in the

Fig. 10. Granulating sore, injected. *h*, a hair, or, margin of sore; *c*, new epithelium at the edge of the sore; *a*, a newly formed vascular loop; *gl*, granulation tissue; *e*, an artery; *c*, a small vein or blood-vessel.

case of a simple wound with loss of substance so extensive as to render the approximation of the surfaces impossible. The hæmorrhage in such a wound is arrested in the same way as has already been described in treating of union by the first intention, and the same process of exudation takes place. The plasma coagulates on the raw surface, the serum drains away, and the fibrin remains behind entangling the migrating leucocytes in its meshes. In union by the first intention, as we have seen, the exudation ceases in a few hours, as the cells, not having been injured to such an extent as to destroy their vitality, being protected from every source of irritation, speedily return to their normal state. In such a wound as we are considering, however, the raw surface must necessarily be in contact with some foreign material, and is thus

exposed to a persistent source of irritation in consequence of which the exudation continues: the migrating cells accumulate on the surface, forming a layer of considerable thickness, and infiltrate the tissues beneath, destroying and taking the place of the superficial parts which have suffered most severely from the injury and the subsequent sources of irritation. The superficial cells of the layer thus formed being exposed necessarily to injurious influences, such as the contact of foreign bodies, the irritation of antiseptic dressings, or of decomposing discharges, &c., perish, become granular, lose their adhesion to each other and float away as pus-cells in the serous discharge. In the pus that is thus formed on the surface of the sore, some freshly migrated white corpuscles still manifesting the characteristic amoeboid movements will always be found. While this process of pus-formation is taking place on the surface, development of new vessels, by the process already described under union by first intention, is taking place in the layers beneath, and at the same time there is an active cell-growth which more than compensates for any loss that may be taking place from the surface in the formation of pus, and the loss of substance which resulted from the original injury is gradually repaired. We have thus developed an actively growing layer of granulation-tissue, that is to say, of a tissue composed of small round cells adhering to each other by a homogeneous intercellular substance, and traversed by an abundant system of thin-walled capillary vessels. In a superficial granulating sore the vessels form loops the convex sides of which are directed towards the surface (Fig. 99). The same differences of opinion exist as to the origin of the cells which appear in the process of healing by second intention that have already been pointed out as existing with regard to the same process in union by the first intention. In whatever way, however, the cells are formed, this much is certain, that "granulation-tissue" is a true tissue, resembling embryonic tissue in its power of growth, by which it fills up the gap left by the loss of substance or formed by the gaping of the surfaces of a wound in which union by first intention has failed. Like any other tissue, "granulation-tissue" is capable of suffering from inflammation if exposed to injurious influences. If removed from every source of irritation, the circulation is as active through the new vessels as it is in those of the original tissues, transudation is not in excess of the requirements of nutrition, and few, if any, of the corpuscular elements of the blood escape through the vascular walls. The growth takes place by the division of the cells of the granulation-tissue, and not by the addition of migrating corpuscles from the vessels. If the tissue be exposed to injurious influences which lower its vitality, exudation takes place, making the granulations swollen, soft or even oedematous, and multitudes of migrating cells find their way to the surface and float away with the serum as pus, mixed with the superficial granulation-cells which have perished and left their adhesion to each other. Thus, when on a raw surface a healthy layer of granulation-tissue is formed, it is theoretically possible that the surface may discharge no pus, only a small quantity of serous fluid escaping owing to the want of an impermeable epithelial covering. In order that this may occur, the delicate cells of which its surface is composed must be protected from every possible source of irritation, whether physical, mechanical or chemical. Such a condition it is practically scarcely possible to obtain, but experience of modern methods of dressing has shown that by proper treatment the quantity of pus and the number of corpuscles it contains may be greatly

there is always some source of infection. Thick creamy pus is no longer regarded as a sign of healthy growth without inflammation, and firmness, being capable of withstanding a severe blow with the finger without giving way, is a sign of healthy growth. A perfectly healthy hand, when it is swollen by inflammatory action, is capable of withstanding a severe blow with the finger without giving way. It is a rule, that granulation-tissue is soft in direct proportion to which it is exposed; and as the repair of continuity, whether subcutaneous or through the medium of granulation-tissue, the process is very great.

The process of union

of granulation-tissue into the fibrous tissue of the skin, from that already described under union by the first intention, however, the effects of the process are proportionately more marked as the size of the sore and the looseness of the structures are greater. The amount of the contraction is the size of the scar left by a sore the size of a half-crown on the face more than a quarter of an inch in diameter, while on the thigh it would be about the size of a sixpence, and on the leg it would be about the diameter of a shilling. The contraction is produced by the healing of extensive granulating tissue after burns and scalds. This process of contraction is an essential part of the healing, and if from any cause, such as want of skin or want of contraction is not possible, the sore ceases to heal.

The covering of the surface of the sore with new epithelium is accomplished by the multiplication of the cells at the margin of the sore. New epithelium is formed from pre-existing epithelium only, and there is no reason to suppose that the granulation-cells can develop into epithelial cells.

When a slough has to be separated before repair can commence, the process is accomplished by the process described under Ulceration (see p. 271).

The phenomena that attend the process above described are as follows. Supposing the case to be one of simple loss of substance produced by a cutting instrument, the raw surface, after bleeding has ceased, continues to secrete a quantity of serum, at first tinged with blood, but gradually becoming colourless; at the same time a glaze is seen to form, due to the exudation adhering to the surface of the wound. The healthy skin around the wound becomes redder than natural, the blush gradually fading as the wound heals. Little further change is observed in the surface of the wound till the end of the second or third day, by which time the surface is distinctly redder; by the third or fourth day, florid red spots begin to appear here and there, and the discharge becomes distinctly purulent. Gradually the red spots coalesce, and the surface becomes covered by the fifth or sixth day with a uniform, highly vascular layer of granulation-tissue. The surface is no longer smooth, the new cells being formed around the vascular little heaps, which give it the granular appearance which has led to the name of "granulation-tissue."

A typically healthy granulating surface presents the following characteristic features. The separate granulations are about the size of split mustard-seeds; they are uniform in size, and of a florid red colour: they will stand a smart blow without bleeding, and, being devoid of nerves, are perfectly free from sensibility. The surface of the sore is very slightly depressed below that of the surrounding skin. The base of the sore is soft. The edges shelf gradually down into the surface, and, if healing is taking place, the new growing epithelium can be seen spreading over the surface of the granulations and giving rise to three zones of different colour. Most internally is a dark red line, darker than the neighbouring granulations. This is due to some slightly increased vascularity beneath the growing epithelium, and to the presence of a very thin layer of perfectly transparent new epithelium-cells covering the granulation-tissue. That this is so can be shown by carefully drying the surface and watching it for a few seconds: the uncovered granulations become moist again almost immediately, while the red line remains dry. Outside the red line is a blue line, resulting from the presence of a thicker layer of epithelium, seen through which the red granulations assume a bluish tint. Outside this again is an opaque white line, in which the new epithelium has been formed in sufficient quantity to be opaque when swollen by the discharges. The discharge varies with the mode of dressing. If some slightly irritant lotion or dressing be applied, thick creamy pus is poured out from the surface; if some non-irritating dressing be applied, thin serous fluid flows away, made more or less turbid by the presence of a few pus-cells. A granulating sore may present a perfectly healthy appearance with both conditions of discharge, but it will usually be found that the red line of new growing epithelium is much wider in those cases in which the dressing is least irritating, as under other conditions many of the young epithelium-cells perish and mingle with the pus-cells in the discharge.

The constitutional symptoms that attend union by the second intention will vary much. The separation of a slough will in all cases be attended with some febrile disturbance if the dead tissue be allowed to putrefy; by antiseptic treatment, however, this may be entirely prevented, and union by the second intention may be accompanied by as little constitutional disturbance as that by the first intention. In cases in which no antiseptic precautions are observed, the febrile disturbance due to the absorption of the products of putrefaction commences on the second day after the injury, and reaches its maximum on the third or fourth. By this time the lymph-spaces are becoming filled with the plastic exudation, and absorption is consequently limited. When the slough is separated and the granulation surface is formed—that is to say, by about the sixth to the tenth day—the fever disappears, as healthy granulations, being devoid of lymphatics, form a barrier to the absorption of septic matter unless it is pent up at some degree of pressure.

The changes taking place in a cicatrix do not cease with its formation. In most cases the contraction of the scar does not attain its maximum until long after the completion of superficial cicatrization, and this may occasion great puckering and deformity. The amount of contraction of a scar is dependent mainly on the size of the original raw surface and on the laxity of the tissue in which it is seated. There is no evidence to justify the assertion so commonly made, that the scars resulting from sores produced by acid caustics and burns contract more than those following the action of alkaline caustics.

or superficial wounds. A circular scar round a tubular organ or excretory duct, as in the intestine, œsophagus, or urethra, leads to narrowing or stricture of the canal, and many of the worst œsophageal strictures result from the accidental swallowing of caustic alkaline fluids. These strictures in most cases gradually become narrower as time goes on, the process of contraction continuing long after the sore has healed.

Further changes are wrought by time in the texture of a cicatrix. When a scar is first formed, it is thin, reddish, or bluish and shining, being composed of imperfectly developed fibrous tissue, covered by a thin epidermic layer. As it becomes older, it assumes a dead-white colour, and becomes depressed, and gradually, but slowly, many years being perhaps required for the change, it "wears out;" that is to say, its structure more closely resembles that of the texture of the part in which it is seated. It never, however, becomes developed into true skin, as neither sebaceous nor sudoriparous glands nor hair form in it.

Coincidentally with these changes, the scar loosens its deep attachments, so that it can be moved more freely upon subjacent parts. It is a long time before the scar attains the vitality of the older structures, if ever it do so completely; and the larger it is, the less its power will usually be. Under the influence of scurvy or syphilis, an old scar is apt to open up again; so also, if a fresh ulcer be formed on the old cicatrix, it will take a longer time to heal than the original one.

5. Union by Secondary Adhesion.—It not unfrequently happens that, although granulations spring up over the sides of a wound, union between the opposed surfaces does not take place. We endeavour to accomplish this by bringing the granulating sides together, and retaining them in that position, when they will cohere; this constitutes union by "*Secondary Adhesion*." In some amputations, and in many plastic operations, cases of hare-lip, cleft-palate, &c., union is occasionally brought about in this manner.

The conditions necessary for this mode of union are, 1st, that the granulating surfaces be perfectly healthy; 2nd, that they be smooth, so that they can be brought evenly into apposition without leaving cavities between them in which pus may accumulate; and 3rd, that after they are brought together they shall be kept at perfect rest.

Circumstances affecting the Healing Process.—In concluding this general description of the process of union of wounds, it will, perhaps, be well to recall briefly some of the conditions essential to rapid and certain healing. In the first place, two conditions are absolutely essential: perfect rest and perfect drainage. No wound can heal by the first intention if its surfaces are frequently rubbed against each other, either by the movements of the injured part or by the clumsiness of the Surgeon in changing the dressings; nor can early union occur if the surfaces are separated from each other by pent-up serous discharge. The third great source of irritation to which wounds are exposed is the presence of decomposing matter between their surfaces. In order that this should occur it is hardly necessary to say that there must be some dead matter there to decompose; living tissues do not putrefy, and amongst living tissues must be reckoned the plastic exudation that mazes a wound, and forms the preliminary bond of union. On the other hand, the serous discharge which is poured out in the first twenty-four hours is decomposable. A perfectly-drained wound with no foreign body in it

blood-clot possesses powerful pyrogenic properties which they attribute to the fibrin-ferment, which it always contains in considerable quantities in a free state. If the ferment be injected in large quantity, other symptoms are developed resembling septicæmia, and often associated with coagulation of blood in the heart or cardiac thrombosis. Clinical experience seems to confirm this view. Large subcutaneous extravasations of blood are usually accompanied by very marked febrile disturbance, and the same has been observed in the transfusion of defibrinated blood. In a large wound, when the drainage is imperfect and an accumulation of aseptic serous discharge takes place, very distinct elevation of temperature is the common result. It is very possible that the application of strong antiseptic fluids to the raw surface of a wound, by increasing the exudation during the first few hours, may slightly add to the fever in some cases, and want of rest or the accumulation of blood-clot in the cavity of a wound may produce a similar effect.

Septic Traumatic Fever is due to the absorption of the chemical products of putrefaction from the surface of a wound. Until granulations, which offer an efficient barrier to the passage of septic products, have sprung up, the raw surface left by a wound absorbs these with the greatest readiness. It has been shown by experiment that salts, such as potassium ferrocyanide, are taken up with great rapidity, and can be detected in the urine within a very short time after their application to a raw surface; the rapidity of absorption is scarcely if at all less from a surface which has been cauterised with a hot iron, but the application of a strong solution of chloride of zinc materially retards, or even prevents, the entrance of the salts into the circulation. The presence of septic matter in a wound, in addition to the constitutional disturbance it directly gives rise to, always causes more or less local inflammation, the products of which no doubt aid in setting up the fever. The severity of septic traumatic fever is proportional to the dose of the chemical products of putrefaction which enters the circulation: consequently it will vary directly with the amount of septic matter present and the size of the wound. If the decomposing matter is put up at some degree of pressure, the rapidity of absorption will be increased. Should the dose be sufficient, the patient may die rapidly from the direct toxic effects of the chemical products of putrefaction, a condition which will be described as one of the forms of septicæmia. Between this and septic traumatic fever the difference is only one of degree. Guided by these facts, the prevention of septic traumatic fever can in most cases be successfully accomplished: first, by perfect drainage of the wound, by which the amount of decomposable matter is reduced to a minimum; and secondly, by the employment of those modes of dressing which will prevent the decomposition of such liquid exudation as may unavoidably remain in contact with the raw surface.

Should septic fever occur it commences on the second day, and reaches its highest point by the third or fourth. At this time the temperature reaches 103 F or 104 F., or even higher. It remains at about the same height, with the usual evening rise and morning fall, till the ninth or tenth day, by which time granulations have sprung up throughout the wound, and the absorption of septic matter ceases more or less completely according to the perfection of the drainage. During the fever the pulse is generally frequent in proportion to the temperature, the disturbance of appetite is great, there is often delirium, especially at night, and rapid loss of flesh. The decline of the

fever, or defervescence, is sometimes rapid, occurring in a period varying from twenty-four to thirty-six hours; but should the wound be one in which perfect drainage is difficult, as in a compound fracture, decomposing pus may be still pent up in parts of the cavity at some degree of pressure, and under these circumstances the decline of the fever will be much delayed, and the symptoms may gradually merge into those of "hectic," attended with the marked evening exacerbations, the profuse sweats, and progressive loss of strength.

Traumatic Delirium presents itself as two distinct types, the one *inflammatory*, the other *nervous*.

In **Inflammatory Traumatic Delirium** there is a quick and bounding pulse, hot skin and head, flushed cheeks, glistening eyes, much thirst, and high fever; in fact, this form is merely the delirium which accompanies the fever consequent upon the absorption of the products of septic or infective inflammation from the wound. Occasionally the patient is violent, tossing himself about the bed, and moving the injured part, insensible to or regardless of pain. More often there is mere wandering of mind; and in mild cases the patient will answer questions rationally. The symptoms are most marked at night, and diminish when the morning fall of temperature commences; they usually set in on the third day, and are most marked by the third or fourth, which, as before stated, is the time at which septic traumatic fever reaches its highest point. The *Treatment* of this form is best carried out by the application of ice to the head; the bowels must be kept well open, and the diet must be light but nutritious. The use of stimulants must be determined by the state of the pulse; when this is very rapid, alcohol often diminishes the delirium and produces sleep; when it is very full and bounding and the patient is young, bleeding from the arm may occasionally be resorted to, but this is seldom required. The patient must be carefully watched, as there is often a constant desire to get out of bed. At the same time that these measures are adopted, local means must not be neglected to subdue the inflammation, and remove any septic matter or pent-up discharges which may be giving rise to the febrile disturbance.

Nervous Traumatic Delirium usually occurs in persons whose constitutions have been broken by habitual excess in drinking; and in fact, it is in most cases, if not always, an attack of ordinary delirium tremens, induced by the shock of the accident. Most commonly the earliest sign is want of sleep, with a restless nervous manner; in some rare cases it is preceded by a fit of an epileptiform character. The pulse becomes quick, small, and irritable; the surface is cool, and usually covered with a clammy offensive perspiration; in cases uncomplicated by an open wound there is usually no elevation of temperature; should there be fever, the gravity of the case is greatly increased. The tongue is white and furred, and there is usually tremor both of it and of the hands. The delirium is of a muttering, suspicious character; the patient is often harassed by spectral illusions, but will answer questions rationally. Traumatic delirium tremens is sometimes very rapidly fatal. I have known it to destroy life in cases of simple fracture in less than twelve hours. In other cases, death takes place after some days from exhaustion; and the fatal termination is occasionally sudden.

A form of *maniacal delirium* is occasionally met with after operations in persons of great nervous susceptibility, who have been exposed to severe mental strain before the operation. It has been not unfrequently observed after

removal of the breast, especially in those cases in which the patient has long concealed her disease, and finally with a great mental effort submitted to the operation.

In the *Treatment* of nervous traumatic delirium, the essential points are to induce sleep and to keep up the patient's strength. The foul tongue and breath are sufficient indications of the necessity of administering a brisk purgative at the commencement of the treatment; in many cases no sedatives will have any effect till the purge has acted. The motions brought away by the medicine are usually excessively foul. The best sedatives are bromide of potassium, morphia, and hyoscyamus. The bromide may be given in twenty-grain doses, repeated every two or three hours. Morphia may be given in quarter-grain doses, repeated at intervals of four hours, till one grain is reached, or till sleep is induced. The effect of the drug must be carefully watched. It is always better to administer it hypodermically when possible, as in some cases it seems to be imperfectly absorbed from the disordered stomach. Hyoscyamus may be administered in half-drachm doses of the tincture, but it is less effectual than morphia. Both morphia and hyoscyamus may be given in combination with the bromide. Hydrate of chloral has also frequently been used; but it is not so safe a drug as those just mentioned, as an excessive dose may kill the patient suddenly. Sulphonal sometimes succeeds in inducing sleep when other drugs have failed. The Surgeon must use his judgment as to the extent to which the sedatives may be pushed. If they fail to act, it is wiser to discontinue them than to run the risk of giving a poisonous dose. Food is even of more importance than sedatives; so long as the patient can take an abundant supply of good liquid nourishment there is hope of his recovery. Solids must be avoided, as the stomach is never in a state to digest them. If there be much depression, it will usually be advisable to administer some stimulant, that to which the patient has habituated himself being the best. It is sometimes convenient to mix the sedative with the stimulant. If the patient be strong, there is no danger in cutting off all stimulants, even in the case of a confirmed drunkard. After sleep has been induced, the quantity of sedatives must be lessened; but it will often be found necessary to continue them for some time, as there will be a tendency to recurrence of the delirium at night.

The patient should, if possible, be put in a room by himself, and watched by a single attendant. If he is violent, he should be at once put in a strait-waistcoat, as it excites him much less to struggle with an inanimate object than with a couple of men. When the strait-waistcoat is firmly applied, the attendant should keep out of sight as much as possible while watching him. If the injury is a broken bone in a limb, the injured part must be fixed firmly in splints well padded with cotton-wool and swung from a cradle; it must on no account be fixed to the bed, for every movement of the patient would then grind the bones together, and perhaps render a simple fracture compound. The patient seems absolutely insensible to the pain caused by such movements.

These two forms of traumatic delirium, the inflammatory and the nervous, are often found more or less conjoined, and in such cases the prognosis is always grave, as exhaustion speedily sets in; stimulants and abundant fluid nourishment must then be freely administered.

of great mental fortitude, or whose minds are actively engaged at the moment of the receipt of an injury.

The condition of shock may gradually increase, the pulse becoming more feeble, the respiration more shallow, and the consciousness more impaired, till death takes place. Fortunately, however, this termination is comparatively infrequent, and occurs only in the most severe injuries. As a rule, after a longer or shorter period, varying according to the severity and seat of the injury and the nervous susceptibility of the patient, the symptoms abate and *reaction* sets in. The surface becomes warmer, the pulse more forcible, the respiration fuller, consciousness becomes more perfect, and colour returns to the face. Vomiting is not an uncommon symptom during the early periods of reaction, and is probably due to some degree of hyperæmia of the brain following the cerebral anæmia which forms a prominent feature of extreme shock. It is not uncommon to find the temperature very slightly elevated during the period of reaction.

The recovery from shock is usually complete. In cases, however, in which it has arisen from violent concussion of the whole system, as in a railway accident, various secondary phenomena may present themselves. These are probably due to actual lesion of the nervous centres, and are fully described in the chapter on Injuries of the Spine.

Pathology of Shock.—There are no characteristic *post-mortem* appearances. The heart, rarely contracted, is more often found full of blood, especially the right side, and the whole venous system is somewhat gorged, unless the patient has lost much blood from the accident. The blood was said by Hunter to remain fluid in some cases, but this is certainly very rare. Rigor mortis is usually well marked. The lungs are engorged, the abdominal viscera congested, but the brain is pale and anæmic.

It is evident that the symptoms above described are more than can be accounted for by any simple theory of cardiac inhibition. The most probable explanation of shock is that it is due to a general exhaustion of the nervous centres consequent upon an extremely violent afferent impulse. In cases of injury this impulse is partly physical, due to the division or crushing of the nerves of the injured part, and partly mental, arising from the fear and sense of suffering caused by the accident. In operations performed under the influence of an anæsthetic, the latter cause would be absent; but as the conductivity of the nerves and the functional activity of the medulla and great centres at the base of the brain are unimpaired during anæsthesia, shock is not avoided, though it is certainly diminished in intensity. The exhaustion of the nervous centres in shock is shown by the general state of muscular relaxation, the loss of tone throughout the vascular system, the feeble action of the heart, and the state of semi-unconsciousness into which the patient is thrown. The general relaxation of the vessels throughout the body, thus occurring simultaneously with an extremely feeble action of the heart, leads to an accumulation of blood, with partial stagnation in those parts of the vascular system which are most dilatable. This is especially marked in the veins of the abdominal cavity. The lungs are also frequently gorged with blood. The abstraction of so large a portion of the blood from the circulation causes anæmia of other parts, and it is thus that the pallor of the skin and the anæmia of the brain may be explained. It has been assumed that the vaso-motor paralysis is most marked in, or even limited to, the parts supplied

of the splanchnic nerves, but there seems to be nothing to justify such an assumption. General vaso-motor paresis combined with feeble action of the heart would necessarily cause accumulation of blood in the large veins of the abdominal viscera, and probably also in those of the flaccid muscles. The wide diffusion of the exhausting effects of an intense afferent impulse is also in accordance with the results of experiment. A very feeble stimulus applied to a nervous centre acts on that centre only, but more powerful stimulation is always found to diffuse itself widely to neighbouring parts. Thus, if a cortical motor centre in the brain be exposed and stimulated by a very feeble electric current, movement is produced in the limited group of muscles corresponding to that centre, whilst a stronger current causes a general convulsion affecting the whole body.

The anemia of the nervous centres aggravates the shock and delays the recovery of the exhausted centres. In fatal cases, it is probably the immediate cause of death. It is necessarily increased by loss of blood.

Causes.—The most serious forms of shock are those that arise from gunshot wounds and railway collisions. The severe and deeply penetrating character of the injuries in the one case, and the suddenness of their occurrence, with the terror inspired by them, in the other, explain the severity of their effects on the nervous system. Shock is partly due to *mental*, partly to *physical* causes. Its severity and continuance are thus materially influenced by the mental condition of the patient, and by the degree and nature of his injury.

In persons of a very timid character, or of great nervous susceptibility, and in those who are liable to the occurrence of syncope—more especially in females—a very trivial injury may produce an extreme degree of shock: indeed, the mere apprehension of injury may, without the occurrence of any physical lesion, give rise to all the phenomena of shock. Thus, Verneuil mentions a case in which sudden death occurred whilst the incision for an intended tracheotomy was being marked with the back of the knife. The state of mind at the time of the receipt of the injury influences its effects on the nervous system. If the patient be anxiously watching for the infliction of a wound, as waiting for the first incision in a surgical operation, all the attention is concentrated upon the coming pain: it is severely felt, and the consequent shock is great. If, on the other hand, the attention be diverted, and the mind in a state of intense excitement, as in the hour of battle, a severe injury may be inflicted, and the patient be unconscious of it, feeling no pain, and experiencing no shock, perhaps not knowing that he is wounded till he sees his own blood. The severity or shock is in a great measure proportionate to the degree of pain attendant upon an injury, and, as sensibility to pain varies greatly in different individuals, so will the attendant shock be greater in some than in others. The sensibility of individuals varies much, and is greatly dependent on occupation, sex, and temperament. Men who live early outdoor lives are less sensitive to pain than those who follow occupations of an opposite kind. The higher man rises in the scale of civilisation, the more acute does his sensibility to pain appear to become, or possibly the less he is able to bear it. A savage probably suffers less than a civilised man from any given injury, and hence may display more apparent fortitude. An hysterical woman probably does not suffer more than one with a more healthy nervous system, but she complains more loudly, for she has her feelings less

under control. Race appears to exercise an influence on pain : some of the native races of India appear to suffer far less than Europeans under surgical operations of a similar kind. There are, however, other conditions besides pain that influence the severity of shock.

The sudden occurrence of a severe injury will cause a *physical impression* independently of any emotion or moral influence. The severity and continuance of the shock are usually proportionate to the gravity of the injury, either from its extent or from the importance of the part wounded. Thus, if the whole of a limb be torn away by a cannon-shot, or crushed by a railway train, the shock will be severe from the extent of the mutilation : whilst, on the other hand, if a man be shot by a pistol-bullet through the abdomen, though the extent of the injury be trifling and only a few drops of blood escape, yet the shock will be severe, owing to the importance of the part injured. The Surgeon not unfrequently employs this fact as an accessory means of diagnosis. Thus, if a man break his leg, and at the same time strike his abdomen, and the shock be very serious and long continued, the probability is that some severe injury has been inflicted upon an internal organ : injury of the viscera occasioning more severe and continued shock than a wound of a less vital part.

The **diagnosis** of shock is usually easy, but it is often difficult to determine after a severe injury how much of the patient's condition is due to loss of blood and how much to shock. Restlessness, deep sighing respiration, a sense of dyspnoea, and a somewhat abundant perspiration, are signs indicating that the patient is suffering to a great extent from loss of blood. If the patient is half unconscious and lies perfectly still, with a very small fluttering pulse and regular shallow respiration, it is probable that his condition is due chiefly to shock. The sickness produced by an anæsthetic may closely resemble shock, but it soon ends in actual vomiting, after which the pulse improves and the pallor diminishes. During an operation, however, this condition often causes the Surgeon great anxiety, which is only relieved by the commencement of vomiting.

3. **Shock with Excitement, or Erethitic Shock.**—Three separate conditions seem to have been described under this name. First, a state of shock not sufficiently severe to render the patient insensible to severe persistent pain, as from an extensive burn or scald. There is, then, restlessness instead of the perfect quiet of severe shock under ordinary conditions. If the shock be more intense the patient may show no signs of pain. One of the worst signs in severe burns of children is an apparently perfect freedom from pain. Secondly, the condition of restlessness, dyspnoea, and excitement from profuse hæmorrhage, combined with some degree of shock, has been described under the above name. Lastly, the term has been applied to cases in which the symptoms of traumatic fever manifest themselves before the exhaustion of the shock has passed away. The ordinary symptoms of fever are present, and amongst them delirium is often prominent. The pulse increases in frequency as the fever develops and at the same time its force becomes less. This condition very commonly terminates in death, apparently from exhaustion.

Treatment of Shock.—If the shock be chiefly mental, the patient will usually rally speedily on being spoken to in a kind and cheering manner, or on having some stimulant administered. If the shock be more severe, and be the result of considerable injury, the patient should be laid in the recumbent

position, and the injured part arranged as comfortably as possible; he should be wrapped up in warm blankets, hot bottles should be applied to the feet, and friction to the hands and surface; a little warm tea, wine, or spirits and water, may be administered, provided the insensibility be not complete; if it be complete, the fluid should not be given, lest it find its way into the larynx. In these circumstances, ammonia should be applied to the nostrils, and a stimulating enema administered, or ten minims of ether may be injected hypodermically, and repeated at intervals of about ten minutes if necessary until the patient begins to rally. When there is much pain associated with the shock, a few drops of laudanum may advantageously be given, or a quarter of a grain of morphia administered hypodermically.

After all large surgical operations, a slight condition of shock is not to be regarded as an evil. The feeble action of the heart favours the perfect closure of the small vessels by coagula, and unwise stimulation is not an uncommon cause of hæmorrhage during the first twelve hours.

Operation during Shock.—Whether an operation should be performed during severe shock is a question of considerable importance. As a general rule, it certainly should be deferred until reaction comes on, as the additional injury inflicted by the operation would increase the depression under which the patient is suffering. In some cases, however, the presence of a crushed limb appears to prevent the patient from rallying, notwithstanding the administration of stimulants. In these circumstances the Surgeon would be justified in operating before reaction came on. Here the administration of ether is extremely beneficial: it acts as a stimulant to the nervous system, and prevents the pain and dread of the operation from still further depressing the patient. In long-continued shock, great care is required in ascertaining that there is no internal injury, such as laceration of one of the viscera, giving rise to the depression, but that the shock is really and solely dependent upon the state of the limb.

Prevention of Shock.—In cases in which an operation is likely to be accompanied by much shock, needless exposure of the body to cold must be carefully avoided, and great care taken to limit the loss of blood by the use of pressure-forceps applied to each vessel as it is divided. Ether should be used in preference to any other anæsthetic, and must be given so as to produce complete anæsthesia. Experiments on animals have shown that after the injection of a very small dose of atropin beneath the skin it is impossible to inhibit the heart by stimulating the vagus. It has therefore been suggested that shock might be prevented in the human subject in this way. We cannot, however, expect much from this treatment, for inhibition of the heart by the pneumogastric probably forms but a small element in most cases of shock as it is met with in practice.

TRAUMATIC FEVER.

The term **Traumatic Fever** has been somewhat loosely applied to any febrile disturbance which follows a wound or severe injury within the first week or ten days after its infliction. The exact nature of this febrile disturbance has occupied the attention of numerous observers, amongst whom may be mentioned Billroth, Bergmann, Volkmann, and Lucas-Championniere. Their investigations have shown that a clear distinction must be made between the fever occurring in subcutaneous injuries, or in wounds following a perfectly

aseptic course, and that occurring as a consequence of the absorption of the products of putrefaction from a septic wound. The term "traumatic" may conveniently be retained to indicate the fact that the fever is directly or indirectly the result of an injury, and we may then speak of Aseptic or Simple Traumatic Fever, and Septic Traumatic Fever. The fever that accompanies a true infective process, either general or local, as in pyæmia or erysipelas, has never been included under traumatic fever.

Aseptic Traumatic Fever. or, as it has been called, "*reactionary fever*," commences as soon as the symptoms of shock disappear. As the patient rallies the temperature rises from the subnormal point to which it had fallen, passes the normal and gradually rises from one to two degrees above it. In the majority of cases it reaches its highest point on the second day, and falls again to normal by the end of the third or fourth day, but it may be prolonged to the sixth or seventh. The highest point is seldom above 101° F. The constitutional disturbance is slight, the patient himself often being unconscious of any feeling of illness. In the case of an open wound, if decomposition of the discharges occurs, the simple traumatic fever is more or less masked by the septic fever which commences on the second or third day, and consequently it is best studied in simple fractures and other subcutaneous injuries. Some important observations illustrating the course of simple traumatic fever have been made by Victor Horsley in cases of simple fractures of the larger bones of the limbs. In 168 such cases he found a distinct febrile disturbance in 91 per cent. In most a rapid rise occurred in the first few hours after the injury, the temperature reaching 99.5° F. to 100° F. The rise then continued more slowly, the maximum—varying from 100° F. to 101° F.—being reached in from twenty-four to forty-eight hours. The temperature in most cases then gradually fell, reaching the normal point before the end of the seventh day.

The exact cause of this febrile disturbance is not yet distinctly known. Lucas-Championnière is of opinion that we must look for it in the nervous system, while Bergmann and others believe it to be due to the local development of some substance possessing pyrogenic properties which is taken up from the injured part either by the blood-vessels or lymphatics. (See also p. 194.)

That a febrile disturbance may be of purely nervous origin seems probable when we consider that which follows concussion of the brain, when there is no reason to suspect any actual laceration, that is to say, when the insensibility is of short duration and the recovery complete. In such cases it will usually be found that the thermometer rises to about 100° F., and falls again to the normal point within twenty-four or forty-eight hours of the injury. There is, however, no evidence to show that a prolonged febrile disturbance can be induced by such stimulation of the sensory nerves as occurs in a wound or other injury. On the other hand, we know that severe pain tends to lower, not to elevate, the temperature.

It seems more probable that in the vast majority of cases, at least, simple traumatic fever is produced by absorption of some pyrogenic substance from the injured area, and we have abundant evidence that such substances are formed. It has been shown by Billroth and others that the fresh aseptic serous discharge from a recent wound, injected into the subcutaneous tissue or vessels of an animal, causes febrile disturbance. Köhler, Edelberg, Bergmann, and others, have also shown that the expressed serum from a fresh

blood-clot possesses powerful pyrogenic properties which they attribute to the fibrin-ferment, which it always contains in considerable quantities in a free state. If the ferment be injected in large quantity, other symptoms are developed resembling septicæmia, and often associated with coagulation of blood in the heart or cardiac thrombosis. Clinical experience seems to confirm this view. Large subcutaneous extravasations of blood are usually accompanied by very marked febrile disturbance, and the same has been observed in the transfusion of defibrinated blood. In a large wound, when the drainage is imperfect and an accumulation of aseptic serous discharge takes place, very distinct elevation of temperature is the common result. It is very possible that the application of strong antiseptic fluids to the raw surface of a wound, by increasing the exudation during the first few hours, may slightly add to the fever in some cases, and want of rest or the accumulation of blood-clot in the cavity of a wound may produce a similar effect.

Septic Traumatic Fever is due to the absorption of the chemical products of putrefaction from the surface of a wound. Until granulations, which offer an efficient barrier to the passage of septic products, have sprung up, the raw surface left by a wound absorbs these with the greatest readiness. It has been shown by experiment that salts, such as potassium ferrocyanide, are taken up with great rapidity, and can be detected in the urine within a very short time after their application to a raw surface; the rapidity of absorption is scarcely if at all less from a surface which has been cauterised with a hot iron, but the application of a strong solution of chloride of zinc materially retards, or even prevents, the entrance of the salts into the circulation. The presence of septic matter in a wound, in addition to the constitutional disturbance it directly gives rise to, always causes more or less local inflammation, the products of which no doubt aid in setting up the fever. The severity of septic traumatic fever is proportional to the dose of the chemical products of putrefaction which enters the circulation; consequently it will vary directly with the amount of septic matter present and the size of the wound. If the decomposing matter be pent up at some degree of pressure, the rapidity of absorption will be increased. Should the dose be sufficient, the patient may die rapidly from the direct toxic effects of the chemical products of putrefaction, a condition which will be described as one of the forms of septicæmia. Between this and septic traumatic fever the difference is only one of degree. Guided by these facts, the prevention of septic traumatic fever can in most cases be successfully accomplished: first, by perfect drainage of the wound, by which the amount of decomposable matter is reduced to a minimum; and secondly, by the employment of those modes of dressing which will prevent the decomposition of such liquid exudation as may unavoidably remain in contact with the raw surface.

Should septic fever occur it commences on the second day, and reaches its highest point by the third or fourth. At this time the temperature reaches 103° F. or 104° F., or even higher. It remains at about the same height, with the usual evening rise and morning fall, till the ninth or tenth day, by which time granulations have sprung up throughout the wound, and the absorption of septic matter ceases more or less completely according to the perfection of the drainage. During the fever the pulse is generally frequent in proportion to the temperature, the disturbance of appetite is great, there is much delirium, especially at night, and rapid loss of flesh. The decline of the

fever, or defervescence, is sometimes rapid, occurring in a period varying from twenty-four to thirty-six hours : but should the wound be one in which perfect drainage is difficult, as in a compound fracture, decomposing pus may be still pent up in parts of the cavity at some degree of pressure, and under these circumstances the decline of the fever will be much delayed, and the symptoms may gradually merge into those of "hectic," attended with the marked evening exacerbations, the profuse sweats, and progressive loss of strength.

Traumatic Delirium presents itself as two distinct types, the one *inflammatory*, the other *nervous*.

In **Inflammatory Traumatic Delirium** there is a quick and bounding pulse, hot skin and head, flushed cheeks, glistening eyes, much thirst, and high fever ; in fact, this form is merely the delirium which accompanies the fever consequent upon the absorption of the products of septic or infective inflammation from the wound. Occasionally the patient is violent, tossing himself about the bed, and moving the injured part, insensible to or regardless of pain. More often there is mere wandering of mind ; and in mild cases the patient will answer questions rationally. The symptoms are most marked at night, and diminish when the morning fall of temperature commences ; they usually set in on the third day, and are most marked by the third or fourth, which, as before stated, is the time at which septic traumatic fever reaches its highest point. The *Treatment* of this form is best carried out by the application of ice to the head : the bowels must be kept well open, and the diet must be light but nutritious. The use of stimulants must be determined by the state of the pulse ; when this is very rapid, alcohol often diminishes the delirium and produces sleep ; when it is very full and bounding and the patient is young, bleeding from the arm may occasionally be resorted to, but this is seldom required. The patient must be carefully watched, as there is often a constant desire to get out of bed. At the same time that these measures are adopted, local means must not be neglected to subdue the inflammation, and remove any septic matter or pent-up discharges which may be giving rise to the febrile disturbance.

Nervous Traumatic Delirium usually occurs in persons whose constitutions have been broken by habitual excess in drinking ; and in fact, it is in most cases, if not always, an attack of ordinary delirium tremens, induced by the shock of the accident. Most commonly the earliest sign is want of sleep, with a restless nervous manner ; in some rare cases it is preceded by a fit of an epileptiform character. The pulse becomes quick, small, and irritable ; the surface is cool, and usually covered with a clammy offensive perspiration ; in cases uncomplicated by an open wound there is usually no elevation of temperature ; should there be fever, the gravity of the case is greatly increased. The tongue is white and furred, and there is usually tremor both of it and of the hands. The delirium is of a muttering, suspecting character ; the patient is often harassed by spectral illusions, but will answer questions rationally. Traumatic delirium tremens is sometimes very rapidly fatal. I have known it to destroy life in cases of simple fracture in less than twelve hours. In other cases, death takes place after some days from exhaustion ; and the fatal termination is occasionally sudden.

A form of *maniacal delirium* is occasionally met with after operations in persons of great nervous susceptibility, who have been exposed to severe mental strain before the operation. It has been not unfrequently observed after

removal of the breast, especially in those cases in which the patient has long concealed her disease, and finally with a great mental effort submitted to the operation.

In the *Treatment* of nervous traumatic delirium, the essential points are to induce sleep and to keep up the patient's strength. The foul tongue and breath are sufficient indications of the necessity of administering a brisk purgative at the commencement of the treatment; in many cases no sedatives will have any effect till the purge has acted. The motions brought away by the medicine are usually excessively foul. The best sedatives are bromide of potassium, morphia, and hyoseyamus. The bromide may be given in twenty-grain doses, repeated every two or three hours. Morphia may be given in quarter-grain doses, repeated at intervals of four hours, till one grain is reached, or till sleep is induced. The effect of the drug must be carefully watched. It is always better to administer it hypodermically when possible, as in some cases it seems to be imperfectly absorbed from the disordered stomach. Hyoseyamus may be administered in half-drachm doses of the tincture, but it is less effectual than morphia. Both morphia and hyoseyamus may be given in combination with the bromide. Hydrate of chloral has also frequently been used; but it is not so safe a drug as those just mentioned, as an excessive dose may kill the patient suddenly. Sulphonal sometimes succeeds in inducing sleep when other drugs have failed. The Surgeon must use his judgment as to the extent to which the sedatives may be pushed. If they fail to act, it is wiser to discontinue them than to run the risk of giving a poisonous dose. Food is even of more importance than sedatives; so long as the patient can take an abundant supply of good liquid nourishment there is hope of his recovery. Solids must be avoided, as the stomach is never in a state to digest them. If there be much depression, it will usually be advisable to administer some stimulant, that to which the patient has habituated himself being the best. It is sometimes convenient to mix the sedative with the stimulant. If the patient be strong, there is no danger in cutting off all stimulants, even in the case of a confirmed drunkard. After sleep has been induced, the quantity of sedatives must be lessened; but it will often be found necessary to continue them for some time, as there will be a tendency to recurrence of the delirium at night.

The patient should, if possible, be put in a room by himself, and watched by a single attendant. If he is violent, he should be at once put in a strait-waistcoat, as it excites him much less to struggle with an inanimate object than with a couple of men. When the strait-waistcoat is firmly applied, the attendant should keep out of sight as much as possible while watching him. If the injury is a broken bone in a limb, the injured part must be fixed firmly in splints well padded with cotton-wool and swung from a cradle; it must on no account be fixed to the bed, for every movement of the patient would then grind the bones together, and perhaps render a simple fracture compound. The patient seems absolutely insensible to the pain caused by such movements.

These two forms of traumatic delirium, the inflammatory and the nervous, are often found more or less conjoined, and in such cases the prognosis is always grave, as exhaustion speedily sets in; stimulants and abundant fluid nourishment must then be freely administered.

REMOTE EFFECTS OF INJURY.

These may be *constitutional* or *local*.

The **Remote Constitutional Effects** of injuries are of a very varied character. In some cases, persons who have met with serious injury will be found to die suddenly, some months after apparent recovery. In others, the general health fails, and an anæmic and cachectic stage supervenes. In other instances, again, the functions of the nervous system become disturbed; convulsive movements or paralytic symptoms of a slight but persistent character develop themselves, and may become progressive. In these cases, the immediate effect of the injury on the nervous system seems to pass off, while a permanent impression is left. The patient never completely recovers from the effects of his injury; he is never "the same man again;" and, although his health may appear to improve from time to time, yet, on careful investigation, it will be found that there has been a continuous train of symptoms indicative of a disordered state of the nervous system. This condition of general disturbance of the nervous system resulting from injuries, especially such as are attended with great mental shock, is designated "traumatic neurasthenia." It will be considered in the chapters on Injuries of the Head and Spine.

Remote Local Effects.—The possible remote local consequences of severe injuries deserve more attention than they usually receive. There can be no doubt that many structural diseases owe their origin to long antecedent injuries. The nutrition of a part may be modified to such an extent by a blow or wound inflicted upon it, as to induce those alterations in the structure which constitute true organic disease. Thus we occasionally find, on death occurring many months after a severe injury, that extensive local mischief, usually of an inflammatory character, is disclosed, which has evidently been going on in an insidious manner from the time of the accident.

In other cases again, a blow may give rise to severe and long-continued neuralgic pains in a part; or it may be the direct cause of structural disease in bones, joints, or blood-vessels; and, lastly, it may be the starting-point of cancerous or other tumours, many cases of which can be distinctly referred to external violence.

CHAPTER IX.

INJURIES OF SOFT PARTS.

THESE consist of *Contusions* and *Wounds*.

CONTUSIONS.

A **Contusion** may be looked upon as a subcutaneous wound. Great disorganisation of the subcutaneous structures may take place, although the skin, owing to its elasticity and toughness, remains intact.

In contusions there is always **extravasation** of blood into the tissues to a greater or less degree. When slight, this extravasation is termed an **ecchymosis**. The blood is not shed outwardly, but accumulates under the skin in the areolar tissue, or in internal organs, presenting in the former situation the ordinary purplish-black discoloration of a bruise. The arrest of the extravasation is due in great measure to the coagulation of the effused blood closing the torn vessels, and in some cases to the pressure it exerts upon their walls; thus allowing the ordinary process of repair of wounded vessels to take place.

CAUSES.—Contusions may result from *direct pressure*, as when a part is forcibly squeezed; from a *direct blow*, usually by a hard blunt body; or from an *indirect blow*, as when the hip-joint is contused by a person falling on his feet from a height.

Compression of the parts injured is always necessary to produce a contusion. This compression may occur between the force on one side and a bone as the resisting medium on the other: or the part injured may be compressed and contused between two forces in action—as when the hand is caught between two revolving wheels; or between a force in action and a passive medium—as by a wheel passing over the limb and crushing it against the ground.

DEGREES.—The amount of extravasation of blood consequent on a contusion will depend upon the force causing the bruise, the vascularity of the part, and to a considerable extent upon the state of health of the individual. In persons out of health, with soft tissues, bruising very readily occurs. Contusions are of various degrees: they may be arranged as follows:—1, of the **Skin only**; 2, with **Extravasation into the Areolar Tissue**; 3, with **Subcutaneous Laceration of the Soft Parts**; and 4, with **Subcutaneous Disorganisation of the Soft and Hard Parts**.

In the *first degree*, the blood is effused merely into the skin, producing *ecchymosis* or bruise; the colour of which varies at different periods from purplish-red to greenish-brown, this variation being dependent upon changes that take place in the pigment as the blood undergoes absorption.

In the *second degree*, the extravasated blood distends the spaces of the areolar tissue, and there coagulates, forming a doughy swelling. In other cases in which the areolar tissue is torn either by the injury or by the

extravasation, a bag of blood may be felt, fluid and fluctuating, under the skin. Under ordinary circumstances the effused blood is gradually absorbed; but if it communicates with the air by an external wound, it will undergo putrefaction, unless special antiseptic precautions are taken to prevent this, and will excite inflammation and suppuration around it, the clots being discharged mixed with pus. In some cases the clot resulting from extravasated blood may ultimately be replaced by new connective tissue, and thus some permanent induration may be left. In other cases the extravasated blood may give rise to a sanguineous tumour, **Hæmatoma**; the blood, which may remain fluid for months, or even years, slowly deposits its fibrin upon the tissues in which it is lying, thus forming an imperfect cyst-wall, while the fluid contents become dark and treacly. According to some pathologists, this imperfect wall may develop into well-formed fibrous tissue, and the contents may become colourless from complete absorption of the blood pigment, and thus a definite cyst with serous contents may be formed in the site of the extravasated blood. In some cases the contents are grumous rather than serous.

In the *third and fourth degrees* of contusion, the laceration and disorganisation of structures often lead to sloughing and suppuration, or to rapid gangrene of the parts, or to hæmorrhage, ending in fatal syncope; or, when the contusion is of an internal organ, this hæmorrhage may prove fatal by taking place into the serous cavities. When the contusion is superficial, the hæmorrhage is subcutaneous, and though abundant, is rarely in sufficient quantity to influence the heart's action. In one remarkable case, however, in which a schoolmaster was convicted of manslaughter for beating a boy to death with a stick, and in which I was called upon to make a *post-mortem* examination, death had evidently resulted, in a great measure at least, from this cause: the subcutaneous areolar tissue of the four limbs being extensively torn away from the fasciæ, and uniformly filled with extravasated blood, whilst the internal organs were in an anæmic condition, even the pulmonary vessels and the cavities of the heart being emptied of blood.

An extravasation of blood, when of any considerable size, is almost invariably followed by a distinct elevation of temperature, often amounting to two or three degrees. It sets in soon after the injury, and subsides by the fourth or fifth day or earlier. The fever of suppuration is more severe, sets in later, and does not subside till the pus is evacuated.

DIAGNOSIS.—This is not always easy. The more severe degrees may be mistaken for incipient gangrene, the discoloration not being very dissimilar, and the resemblance being sometimes increased by the formation of blebs upon the skin containing serous fluid more or less darkly coloured with blood; but the part, when simply contused, preserves its temperature and vitality. In some cases the extravasated blood has a hard circumscribed border of clot, and is soft in the centre, which in the scalp resembles somewhat a depression in the subjacent bone.

The diagnosis of old cases of extravasation, leading to hæmatoma, from abscess or malignant disease, is not always easily made by tactile examination alone; but the history of the case, exploration with a grooved needle, and examination of the contents of the tumour under the microscope, will always clear up any doubt that may exist.

TREATMENT.—In the first two degrees of contusion our object should be to arrest the hæmorrhage from the ruptured vessels as speedily as possible, and

afterwards to promote the absorption of the extravasated blood. For the first purpose cold applications are of especial service. Ice may be applied in severe cases, but its use must not be continued too long, lest it lead to sloughing of the bruised tissues. In slight cases a lotion composed of one part of spirits of wine to eight or ten of water may be constantly applied. After all hæmorrhage has ceased, cold is of little use in promoting absorption, and the part may be wrapped in cotton-wool or hot fomentations may be applied. Leeches should not be applied to a bruised part; they cannot remove the blood that has already been extravasated, and they often set up irritation, which leads to suppuration. A bag of blood, however soft and fluctuating it may feel, should not be opened so long as there is any chance of its being absorbed. If once it be punctured and unpurified air or water be allowed to enter, suppuration may be set up in it. The fluid blood may, however, in such case be safely removed by means of the aspirator, a large needle being used, and the puncture being closed with collodion. If signs of inflammation occur, the parts becoming red, hot, and throbbing, free incisions should at once be made with antiseptic precautions.

In the third and fourth degrees of contusion, it is often useless to attempt to save the life of the injured part; but, if this is attempted, much may be done to prevent the fever and suppuration that sometimes attend the separation of the sloughs. The skin, being in such cases unbroken, must be washed with a solution of carbolic acid (1 in 20), or perchloride of mercury (1 in 5000), after which an antiseptic dressing may be applied, beneath which the sloughs will separate with scarcely any febrile disturbance, and but little suppuration.

Disorganising contusions of the most severe kind may be recovered from *provided there be no external wound*, even though the soft structures of the limb or part be extensively crushed, the bones comminuted, and the joints opened. It is not the subcutaneous lacerations and disorganisations that are to be dreaded; so long as the main blood-vessels of the part injured are intact, these may be recovered from. The admission of air, bearing with it the causes of decomposition, into the interior of a badly injured limb constitutes the great danger. If this can be avoided there is little fear of undue inflammation being excited; but if impure air or water be admitted to the lacerated tissues, putrefaction followed by suppuration and sloughing may be set up, and the safety of the patient thus seriously imperilled. In such cases as these, amputation is usually the sole resource, unless the progress of the mischief can be arrested by efficient antiseptic treatment.

The difference between the effects of a subcutaneous laceration and one accompanied by open wound is well exemplified in the cases of a "simple" and a "compound" dislocation. In the former case, although the ligaments and muscular muscles are extensively torn, often with great extravasation of blood, repair takes place without any serious trouble; whilst in a compound dislocation, in which air has been admitted and has given rise to putrefaction of the extravasated blood and the inflammatory exudation, the most extensive suppuration necessarily ensues, and joint, limb, or life is in great danger of being lost.

Contusions of internal organs are always very serious, and require special treatment, according to the part that is affected and the extent of its injury.

Strangulation of Parts.—Strangulation may be sudden and complete, as

when a *varix* or *pile* is ligatured by the Surgeon. The circulation is then immediately arrested, and gangrene results, not preceded by swelling or marked alteration in colour. Accidental strangulation is more commonly gradual. In such cases, the first effect of the constriction is to prevent the return of the venous blood; this occasions serous effusion and oedematous swelling. If relief be not afforded to the circulation by the removal of the constriction, distension of the vessels, stagnation of the blood, and gradual loss of vitality of the part terminating in gangrene will ensue. In many cases in which the strangulation is relieved by the Surgeon, the loss of vitality is far advanced but not complete, and the restoration of the circulation is then followed by inflammation, varying in intensity with the degree of damage that the tissues have suffered. This is, indeed, merely an illustration of the fact experimentally demonstrated by Cohnheim, that arrest of the circulation in a rabbit's ear gives rise, when the circulation is restored, to inflammation, the intensity of which can be determined by the duration of interference with the flow of blood. The most familiar example of this condition in actual practice is the inflammation of the gut that so frequently follows reduction of a strangulated hernia.

The treatment of strangulation consists in at once dividing or removing the cord or ring, as the case may be. Usually this is easily done, but in some cases it is attended with no little difficulty. This happens especially when a small ring has been hurriedly put on a wrong finger, or when the penis has been drawn through a brass ring. In such cases as these the swelling renders the removal of the foreign body difficult. The finger-ring may usually be removed by slipping a director under it, and clipping or filing it across upon this. Sometimes the following popular plan may advantageously be adopted. A strong silk thread is carefully bound round the finger as tightly as possible from the tip down to the ring, under which the free end is carried with a needle: the thread is then slowly untwisted, and the ring is thus carried upon it off the finger. Curtain or other brass rings compressing the root of the penis have been known slowly and gradually to cut through the organ, without destroying its vitality or rendering the urethra impervious, but so fortunate a result is altogether exceptional; in the great majority of such cases, unless the ring be speedily cut off, mortification of the organ will ensue, and may be followed, as it has been in some instances, by the death of the patient.

Subcutaneous Wounds.—The remarks that have just been made with respect to the effects of the admission of air into extravasations of blood and subcutaneous lacerations or contusions, apply with equal force to subcutaneous wounds; indeed such lacerations, ruptures, and injuries are, properly speaking, subcutaneous wounds: that is to say, bones, muscles, ligaments, tendons, and blood-vessels may be broken, torn, contused, and ruptured, and yet, if the skin covering the parts be unbroken, complete repair may take place without the inflammation at any time passing beyond the simple traumatic or adhesive stage, and without more than the slight degree of traumatic fever inseparable from all serious injuries, which in the slighter injuries would not be recognisable.

It takes advantage of this most important fact in many of his operations which are performed *subcutaneously*; that is to say, the narrow force is introduced through a puncture in the skin, tissues are

freely divided, and on the withdrawal of the knife the wound is so closed either by the approximation of its valvular edges, or by the pressure of a compress, that the entrance of air is prevented, and thus healing takes place by the first intention, without constitutional disturbance, as in a subcutaneous laceration. This is the principle on which the operation of tenotomy is performed.

The only treatment needed in a subcutaneous wound is rest and protection of the skin. The unbroken skin is a more certain antiseptic than any surgical dressing.

OPEN WOUNDS.

A wound may best be defined, in the words of Wiseman, as "a solution of continuity in any part of the body, suddenly made by anything that cuts or tears, with a division of the skin."

Surgeons divide wounds into five kinds, **Incised, Lacerated, Contused, Punctured, and Poisoned.**

INCISED WOUNDS.

Incised wounds are those made by a sharp-cutting instrument such as a knife or sword. They may vary in extent from a simple superficial cut to the incision required in amputation at the hip-joint. They may be simple, implicating merely integument or integument and muscle; or they may be complicated with injury of the larger vessels and nerves, or of important organs.

Symptoms.—All incised wounds give rise to three symptoms; viz. Pain, Hæmorrhage, and Separation of the lips of the wound.

The **Pain** in an incised wound is usually of a cutting, burning, or smarting character. The intensity of the pain varies with the abundance of the nervous supply of the part; a wound of the hand, for instance, is much more painful than one of the skin of the back.

The amount of **Hæmorrhage** necessarily depends upon the vascularity of the part as well as on the size of the wound. The proximity of the part wounded to the centre of the circulation, or to a large vessel, has also a very considerable influence, different parts of the same tissue bleeding with different degrees of facility; thus the skin of the face yields when cut more blood than that of the leg. Again, the same parts will pour out a larger quantity of blood when the vessels are dilated in consequence of local irritation than when they are in their normal condition.

The **Separation of the Lips of the Wound** depends on the tension and the position of the part as well as on the elasticity and vital contractility of the tissues; it is also influenced by the direction of the incision, according as this is parallel to the axis of a limb or muscle or across it. It is greatest in those parts that are naturally the most elastic or that possess the highest degree of tonicity; thus the muscles when cut retract some inches, the arteries and skin gape widely when divided, whereas in the case of ligaments or bones, no retraction takes place.

MANAGEMENT OF INCISED WOUNDS.—In the treatment of an incised wound, we must always endeavour to procure union by first intention (p. 286) between a portion, if not the whole, of the surfaces, for reasons already given. This

result depends partly upon the constitution of the patient ; it is an error to suppose that success is entirely dependent on local conditions and the management of the wound itself. In some constitutions it is impossible, under the most favourable circumstances, to obtain it. The sounder the constitution, the more readily will union by the first intention take place ; and in all cases it is favoured by the removal of all sources of irritation from the system, and by the adoption of a plain and nutritious diet. Repair, like all other physiological processes, is attended with an expenditure of force directly proportional to the extent of the injury to be repaired, hence a lowering plan of treatment is to be avoided, though the opposite error of overstimulation is equally to be deprecated. Before any operation, when possible, the patient should be prepared by being kept for some days upon a plain diet. He should take moderate exercise, and regular action of the bowels should be ensured. The condition of the kidneys should also be ascertained by examination of the urine. In cases of accidental wound we must keep the patient quiet, put him on a moderate diet, and be very cautious in the administration of stimulants, as they have a great tendency to interfere with union by the first intention by increasing the force of the heart and exaggerating the early exudation.

Local Treatment.—In the treatment of wounds the first four days form the most important period, and the fate of the wound, whether it shall heal by first intention or by the slower process of granulation, is practically determined in the first twenty-four hours. It has already been pointed out in the chapters on Inflammation and Repair that, as the necessary result of the injury done by the knife, a limited traumatic inflammation is set up, accompanied by abundant exudation of liquor sanguinis and migration of corpuscles ; the liquid exudation coagulates, the serum drains away, and the coagulated fibrin with the white corpuscles remains behind, forming the “plastic exudation” which serves as the first bond of union. This process *must* occur, but it should be completed within the first twenty-four hours, at the end of which time the tissues should have recovered from the damage done by the knife, exudation should cease, and the period of traumatic inflammation should be at an end. Should any fresh source of irritation be brought to bear on the surfaces of the wound the inflammation will persist, the migration and exudation will continue, pus will form instead of the desired plastic exudation, and all adhesion between the surfaces is prevented. The sources of irritation against which we have to guard are—first, *mechanical*, viz. the presence of foreign bodies, the tension from accumulation of blood-clot or discharges, and friction of the surfaces against each other ; secondly, *chemical*, the products of putrefaction and the persistent action of powerful antiseptics ; and thirdly, *specific infective poisons*, as erysipelas, hospital gangrene, some forms of pyæmia and septicæmia. It is evident, therefore, that, in accordance with these principles, the following are the essential features of the treatment of a wound:—1. Arrest hæmorrhage perfectly ; 2. Remove all foreign bodies and clean the wound ; 3. Bring the surfaces accurately into contact ; 4. Provide perfect drainage for the serous discharge which must be poured out during the first twenty-four hours ; 5. Maintain perfect rest of the part ; 6. Prevent decomposition of any discharge that may form between the surfaces, avoiding the constant action of an irritating antiseptic, and guard the patient against the chance of infection from unhealthy or specific inflammations in the wounds of others.

The healthy traumatic inflammation which results from every wound is very limited in extent, and consequently gives rise to such slight local symptoms that it may clinically pass unnoticed, and it has sometimes been ignored; the term "inflammation of a wound" being applied to the process only when it extends more widely so as to cause redness, swelling, heat and pain easily recognisable by the most superficial observer. (Clinically this may be convenient, but pathologically it is inaccurate. The process by which the plastic exudation is formed is an example of simple traumatic inflammation not spreading beyond the area injured; the later process is a spreading inflammation due to various sources of irritation which have been allowed to act on the wound after its infliction.

There is no subject in Surgery which has undergone more frequent modifications from the earliest periods of which we have record than the local treatment of wounds. The first, and perhaps the instinctive, method of treating a wound was to close it up at once and to exclude the air by means of a mass of clay, of chewed leaves, or of cow's or camel's dung. The wound was further protected from the air by pouring oil into it, and putrefaction was limited by the use of wine or balsams. At a later period in the history of our art, tents of various kinds were used in order to prevent the injurious accumulation of discharges, which might decompose and putrefy. The closure of the wound and the prevention of putrefaction in its discharges by the use of spirituous and stimulating antiseptics, or by facilitating the escape of the secretions, were the means employed from the most remote antiquity. That these methods were in many cases highly successful there can be no doubt; and it is still these four great principles, the closure of the wound, the prevention of putrefaction, the facilitation of the escape of discharges, and the maintenance of perfect rest between the opposed surfaces, that guide us in the treatment of all wounds, however different may be the means by which we endeavour to carry them out.

In the local treatment of all incised wounds there are six chief indications, which will be considered in the following order: 1, the *Arrest of Hemorrhage*; 2, the *Removal of Foreign Bodies*; 3, the *Coaptation of the Sides of the Wound*; 4, the *Provision of Perfect Drainage*; 5, the *Maintenance of Perfect Rest*; 6, the *Prevention of Decomposition of the Discharges and Infection of the Wound*. These we shall consider more in detail.

1. **Arrest of Hemorrhage.**—If bleeding be general from the surface it may be stopped by exposure to the air, by elevation of the wounded part, by accurate and firm coaptation maintained by the pressure of a well-applied bandage, and by the use of cold, heat, or other styptics. Arterial bleeding must be arrested by the means described in Chapter XIV. In making choice of a hæmostatic, preference is to be given to that which will interfere least with union by the first intention. Thus, among styptics, hot water or cold, in the shape of ice or of rags wrung out of cold water, is to be preferred to others, such as the perchloride of iron, which are all more or less caustic and irritant. Again, torsion should be employed when possible rather than other means; and if the ligature be used, it should be of some material which can be absorbed and will not offer any obstacle to union by the first intention.

2. The **Removal of Foreign Bodies**, such as dirt, pieces of stone and glass, spicula of bone, coagulated blood, &c., is best effected by allowing

a stream of water, to which some efficient antiseptic, as carbolic acid, corrosive sublimate, or iodine has been added, to fall upon the part from a sponge or irrigator, all rough handling of the wounded tissue being avoided as much as possible. Sharp and angular bits embedded amongst the tissues should be removed with forceps. Above all, this cleansing of the wound is to be done thoroughly, and once for all; a comparatively insignificant body, if overlooked at this time, may effectually prevent adhesion, whilst disturbance of the wound after it has been once closed destroys the layer of plastic exudation which ought to form the early bond of union.

3. The next and most important indication to fulfil, is the **Coaptation of the Opposed Surfaces** as accurately as possible.

As a general rule, the sides should not be brought together until all hæmorrhage has ceased; if, however, there is but slight oozing, this may be arrested by their approximation, and the pressure thus exercised on the bleeding vessels.

The surfaces should be gently brought together so as thoroughly to exclude all air and superfluous moisture from the deeper portions of the wound, the skin-margin being the last to be adjusted; due attention should at the same time be paid to relaxing the parts by position, so that there may be no gaping of the lips nor tension on the sides of the wound. For the purpose of keeping all in position, *sutures, plasters, and bandages* are employed.

Sutures are the best means we have of bringing the edges of a wound in close apposition, but if drainage be not carefully attended to they may favour bagging, by causing superficial union, whilst the deeper parts still gape. A suture is in itself almost unirritating, but it can become irritating in two ways—first, by being applied too tightly, or by becoming tight in consequence of swelling, and thus causing tension; and, secondly, by absorbing the products of putrefaction, and thus acting as a chemical irritant. The first condition is common to all sutures, of whatever material they may be made; the second can be avoided by the use of metallic or other non-absorbent substances, and by efficient antiseptic treatment of the wound. The chief non-absorbent materials employed are well-annealed silver wire of various degrees of stoutness, silkworm-gut, and horsehair. In cases treated antiseptically silk is largely used for sutures; it should be that known as dentists' or twisted silk, and should not be waxed. It may be thoroughly sterilised by boiling for half an hour, and should then be kept ready for use in carbolic acid solution (1 in 20). Silkworm-gut and horsehair are excellent materials for sutures, and are readily made aseptic by immersion for a few minutes in carbolic lotion (1 in 20); they are especially useful in plastic operations on the face. Fine chromicised catgut has the great advantage of not requiring to be taken out, as the deep part of the stitch becomes absorbed if it is protected from decomposition. A non-absorbent suture should always be used in cases where much discharge is expected or where the antiseptic method cannot be employed; thus silver wire is the best suture for the operation of cleft palate. The thickness of the suture will vary with the purpose for which it is used: thus for the support of large flaps in an amputation the suture must be thick; whereas for the accurate adjustment of the skin in a wound or plastic operation about the face the finest sutures are employed. Needles of every variety are used; they may be straight or variously curved, and it is sometimes convenient to have them set in a handle with the eye near the point.

instead of in the ordinary position. For silver sutures a special form of needle is used, having grooves to receive the wire when doubled back after passing through the eye.

The modes of applying sutures are various; but the one most commonly employed in all cases involving the integument is the **interrupted**, which consists of the introduction of as many single stitches as may be necessary to close the opening. The distance between the stitches must be determined by the amount of tension and by the necessities of drainage. If there is even moderate tension, it is better to insert a few sutures of a thicker material, or "sutures of support," extending deeply into the subcutaneous tissue, the needle being made to pierce the skin an inch or more from the edge of the wound. These sutures are first tightened to such an extent as just to approximate the lips of the wound, which may afterwards be brought more accurately into contact by finer stitches or "sutures of apposition" (Fig. 27). If ample provision is made for drainage by the use of tubes the edges of the wound may be brought very closely in contact, otherwise in large wounds there should not be less than one inch between the stitches. When, as in some plastic operations, one edge of the wound is at a higher level than the other, if it is desired to depress the higher edge, the stitch must be so passed that it shall include a larger piece of the lower: if to raise the lower edge, the chief hold must be on the higher. In longitudinal wounds, the first stitch should be inserted in the centre: but, if there be any angles, as must be the case after crucial incisions, the extremities should be first closed. The fastening is effected in the case of silk by tying a reef-knot, and in that of wire, by tying a half knot and then crossing the two ends over each other, by which two small hooks are made which hold very firmly: in both instances, the ends are cut off short. The knot or twist must not lie over the line of incision, but on one or other side of it. The time that the sutures should be allowed to remain must depend greatly on the nature and progress of the wound. A septic silk stitch must be removed in from two to three days; an aseptic silk or a silver suture may be left in as long as it serves any useful purpose, provided it is causing no irritation. A tight stitch necessarily causes irritation; in from twenty-four to forty-eight hours it will be surrounded by a blush of redness extending an inch or more from the edge of the wound, and by the third day it will have commenced to cut its way out by ulceration. When this occurs, no good purpose can be served in most cases by retaining it, and it should at once be removed. All deep stitches should as a rule be removed not later than the third day. In withdrawing sutures, the knot or twist should be raised by forceps, and the thread divided on one side of it; gentle traction on the knot, the forefinger of the other hand being placed close to the point of exit in the skin, to prevent disturbance of the newly formed granulation-tissue, will then suffice to draw the suture out. When wire has been used, the bend in it should be straightened as much as possible before pulling it out.

In the **continuous suture**, or glover's stitch, the thread is carried on from stitch to stitch, instead of being detached from the needle, and fastened off as in the interrupted suture. Silk is most conveniently employed. The chief disadvantage of this form of suture is, that, if one stitch cuts through, the others may become relaxed. It is, however, often used for the closure of large wounds, after the insertion of a few deep interrupted sutures of support.

The *Button-Suture* is sometimes used as a deep supporting stitch where there is much gaping of a large wound. It consists of a thick silver wire penetrating deeply through the subcutaneous tissue and passing through the skin from one inch and a half to two inches on each side of the wound. Each end of the wire is passed through an oval piece of sheet lead perforated with a hole in its centre; on the button are projecting wings round which the wire can be twisted after it has been brought through the hole. The two buttons are drawn together and maintained in position by twisting the wire round the wings in such a way as to bring the edges of the wound in sufficient apposition to allow of the finer stitches being inserted without undue tension. The button diffuses the pressure over the whole area upon which it presses, and thus a considerable degree of traction may be applied without causing sloughing. It is especially useful after the excision of malignant tumours with a portion of skin.

The *twisted* or *figure-of-8 suture* is frequently used in cases of hare-lip, and occasionally in other plastic operations. A slender soft iron pin, with a steel point, is introduced through each lip of the wound, at a distance of about half an inch from the margins; and whilst the edges are held in contact, a piece of silk twist is passed in a figure-of-8 round the pin, care being taken not to draw it too tight, nor to compress the soft parts between the needle and the thread, lest sloughing ensue. The projecting ends of the pin are now cut off with pliers, and the skin beneath them protected with plaster.

The pin takes the tension off the suture, so that it is less likely to cut its way out than the interrupted suture. It should be withdrawn in about forty-eight hours.

In closing extensive wounds involving the division of muscular planes, it is often advisable to bring the separate layers into apposition by **buried sutures** of silk or catgut. These must be very carefully sterilised, and are left *in situ*.

Plasters are very rarely employed as a means of bringing the edges of a freshly-made wound into contact. They are, however, sometimes very useful for supporting the tissues on either side of a wound and thus ensuring more perfect rest, and may advantageously be used to prevent the wide separation of the edges of a wound, in which union by first intention has failed to take place. Resin, soap, and isinglass plasters all possess peculiar properties, fitting them for use in particular cases. The American rubber-plaster, which adheres with great tenacity without being either wetted or warmed, will be found very convenient. It will not stick to a wet surface, but if once applied is not easily loosened by discharges, as it is a waterproof material.

Strapping used in an antiseptic dressing should be previously dipped in a basin containing a pint-and-a-half of boiling water in which an ounce of carbolic acid has been dissolved. All superfluous hair having been removed, and the surface dried, each strip should be laid down evenly between the points of suture when these have been used, so as to compress each side of the wound equally. In removing the plaster both ends should be raised at the same time towards the wound, and the strip should then be taken off without either lip of the wound being unduly dragged upon. The strips should be allowed to remain undisturbed as long as possible, and each one replaced before the next is removed.

When the edges of the wound have been brought together, nothing main-

ains the perfect coaptation of the deeper parts so perfectly as the uniform elastic pressure of a mass of cotton-wool, or some similar substance, surrounded by a bandage evenly and firmly applied. This forms a most important feature in some of the methods of treating wounds, to be described immediately.

4. **The provision for Perfect Drainage.**—In every wound which has been closed by sutures there is a danger that the deep part may become distended with blood or serous exudations. Before finally closing a wound it is essential that the hæmorrhage be very thoroughly arrested, and considerable time must often be spent in obtaining this result. Again, by the firm elastic pressure of a large cotton-wool dressing, the early serous exudation can be greatly diminished, the surfaces of the wound being brought into perfect apposition, and the vessels and lymph-spaces closed early by plastic exudation. By most careful attention to these two points—thorough arrest of hæmorrhage and application of uniform pressure—extensive wounds may heal throughout by first intention without any provision for drainage having been made. Such a result cannot, however, be ensured; oozing of blood may occur after the wound is closed, and in many situations it is impossible to apply uniform pressure sufficient to influence the amount of the serous exudation. Hence provision must be made for drainage in most cases, and the value of a "drainage-tube" cannot be overestimated as a safeguard against the accumulation of decomposable fluids in the wound, which prevents the cohesion of its opposite sides, and exposes the patient to the danger of septic contamination. In a wound healing by first intention the tube has served its purpose at the end of twenty-four or forty-eight hours, and it may then be removed. Its use should never be omitted, if the wound be deep and irregular, or if there be danger of bagging under a flap. In operations the wound should, whenever possible, be made in such a direction as to facilitate drainage.

5. **The Maintenance of Perfect Rest.**—One important point in the management of every wound is to maintain the injured structures, as much as possible, in a state of rest. This is to be done by position, by refraining from disturbing the parts unnecessarily, and by the adoption of some mode of dressing that requires to be changed but seldom. In some cases, *Compresses* of wool or gauze may be so disposed as to aid in keeping the sides in apposition: the *bandages* should be applied over them so as to exert a steady well-regulated pressure, without impeding the free circulation of blood in the part. The elastic pressure of a large mass of cotton-wool as applied in some of the forms of dressing to be described hereafter maintains rest in the highest perfection.

In the treatment of wounds on the limbs the use of a *splint* is often necessary.

6. **The prevention of decomposition of the discharge and of infection of the wound** must be carried out by means founded on the principles already laid down when treating of the causes (p. 172 *et seq.*), and the prevention, (p. 204 *et seq.*) of inflammation.

METHODS OF TREATING WOUNDS.

It is impossible to make more than brief reference to those various methods employed by Surgeons in the treatment of wounds before the introduction of the antiseptic method by Lister.

The **Occlusion Methods** had for their object the exclusion of air from the wound, but the means adopted to obtain this result necessarily shut in the discharges, and thus tension, followed by inflammation and suppuration, commonly occurred. There is no real analogy between this mode of treatment and the process of scabbing, in which the discharge drains away and dries to form the scab. The application of an occlusive dressing can only be justified in the treatment of a small clean cut, and many wounds which might have healed without trouble, if properly treated, have been rendered serious by the "bit of sticking-plaster" applied in a chemist's shop.

Collodion is the only material commonly employed in the present day as an occlusive dressing; in applying it the edges of the wound must be carefully held together and the skin around it thoroughly dried. *Styptic Collodion* has the further advantage of being hemostatic and antiseptic.

The **Open Treatment** consisted in the application of no dressing of any kind. Wounds so treated often run a perfectly aseptic course, but the result could not be relied upon. Rest was obtained with some degree of perfection, and the drainage was often good, but, if the discharges were too copious to allow them to dry, decomposition with suppuration almost necessarily followed.

The **Simple Water Dressing** advocated by Liston was a mode of treatment extensively adopted until less than thirty years ago. This method differed from the open treatment only in that the wound was covered with lint, which was kept constantly moistened with water. The discharges were thus prevented from drying, and putrefaction was encouraged. I have, however, seen many large wounds such as those of amputations, or after excision of the breast, heal almost by the first intention, without any suppuration except along the track of the ligatures.

The **Dry Lint Dressing** was used by Syme and many others before the introduction of antiseptic treatment. It consisted of a pad of dry lint placed on each side of the wound, so as gently to press the surfaces together without interfering with the exit of discharge. Over these was placed another piece of lint about three layers thick, and the whole was surrounded with a bandage. This was left untouched for three or four days, by which time it was usually soaked with the discharges and had become more or less offensive from decomposition. This mode of treatment secured rest, apposition, and drainage, and perhaps delayed decomposition by drying the discharges to some extent. Very good results were often obtained by it, but suppuration, followed by pyæmia, was no uncommon occurrence.

The **Cotton-Wool Dressing** was introduced by A. Guérin, of Paris. In this mode of treatment, the wound having been cleaned and its edges carefully approximated, and if necessary a drainage-tube inserted, the whole part is enveloped in a huge mass of cotton-wool, a foot or more in thickness. Over this a bandage is forcibly applied, so as to compress the wool to about half its previous thickness. The dressing is then left undisturbed for a fortnight or three weeks. The temperature is carefully watched during this period, and should there be any considerable rise after the third day the dressing must be removed at once. Severe pain would be another indication for looking at the wound. The principle of the dressing is this: accurate coaptation of the surfaces and the most perfect rest are obtained by the uniform elastic pressure of the cotton-wool; the early exudation is much diminished in quantity, partly

by the pressure and partly by the early adhesion of the opposed surfaces, and such discharge as there is escapes between the edges of the wound and is absorbed by the wool and there dried, and thus prevented from decomposing : all infection from without is prevented by the filtration of the air should any circulate through the mass of cotton-wool. By this treatment admirable results are often obtained, the wound healing rapidly and painlessly, leaving a simple linear cicatrix. The prevention of putrefaction is, however, uncertain : if the discharge is small in amount, and becomes completely dried, the case will run an absolutely aseptic course : more commonly there is a very offensive smell, sometimes that of ordinary putrefaction, sometimes quite peculiar. With this there is some septic fever during the first few days. Guérin's dressing has undergone some modifications, and its principles, as will be seen hereafter, have been adopted in some forms of antiseptic dressing. The substitution of absorbent wool, *i.e.* cotton-wool completely deprived of grease, for common cotton-wool, has rendered the drying of the discharge and the consequent prevention of decomposition more perfect, but even with this it is by no means certain.

In all the foregoing methods no chemical antiseptic is used in the dressing ; and the prevention of all evils which follow decomposition of the discharges is but imperfectly accomplished.

The **Antiseptic Treatment of Wounds**, as introduced by Lister, has for its object the absolute prevention of decomposition of the discharges by the application to practice of the germ theory of decomposition. The theory has already been described so fully that it remains only to show the mode of its application. The practice does not necessitate the use of any special antiseptic agent, nor of any special material for dressing : any method of treatment which entirely prevents decomposition, without the constant contact of the antiseptic agent with the raw surface, carries out the principle. The term "aseptic" has sometimes been applied to the various methods of treatment in which the prevention of decomposition is carried out in this way to distinguish them from those in which the cavity of the wound is constantly irrigated or frequently syringed out with an antiseptic fluid.

Every accidental wound which has been exposed for some time before it is seen by the Surgeon will probably contain, deposited in it from the air, the organisms which cause decomposition. Still more certainly will this be the case if dirt has been carried in by the instrument inflicting the wound, or if it has been washed with common water. The first step in such a case is, therefore, to destroy the organisms by washing the surfaces with an efficient antiseptic solution. In the original antiseptic treatment, as introduced by Lister, carbolic acid was the agent used, but at the present time solutions of perchloride of mercury are sometimes employed, and some Surgeons prefer a weak solution of iodine (*Tr. Iodi ʒij. Aq. Oj.*). In the following description of an antiseptic dressing carbolic acid only will be mentioned, but it must be remembered that a solution of perchloride of mercury, 1 in 1000, may be substituted for the carbolic acid 1 in 20, and one of 1 in 2000 of the former for 1 in 40 of the latter, except in the spray and for instruments. In a prolonged operation or in irrigating a large wound it is safer to use a still more dilute solution of mercury. If the injury be a simple incised wound with smooth surfaces, this may be done with a sponge or with a simple irrigator ; if it be irregular, as in a compound fracture, it is best carried out by means of a syringe with a piece of soft india-

rubber tubing on its nozzle. The tubing is stiff enough to penetrate any existing cavity, but not so stiff as to force a way for itself. Care must be taken, in injecting the wound, not to squeeze the lips together so as to cause high pressure in its cavity, for the lymph-spaces in the neighbourhood may become injected with the solution, and unpleasant inflammation may follow. The whole of the parts which will be covered by the dressing should be well washed with the solution. If the wound be on the hand or foot, great care must be taken to clean the nails and between the digits. If the wound is on the head or any other hairy part, the hair must be cut away and the skin shaved. Then, protecting the wound as far as possible, the surrounding skin must be cleaned with soap and hot water or with a weak solution of ammonia and then well washed with the antiseptic solution.

In the case of an operation, the *skin* is first cleansed with soap and hot water, and, if it be unusually greasy, turpentine or ether may be used. Carbolic lotion (1 in 20) is now freely applied around the seat of the intended incision; this is far preferable to mercurial lotions, which run off greasy skin without thoroughly wetting it. The part should, if possible, be wrapped in a towel wrung out in the 1 in 40 solution for at least half an hour before the operation.

This being done, it is necessary to prevent the entrance of organisms into the wound during the operation. The possible sources of contamination are the Surgeon's hands, the instruments, the sponges, the ligatures, and, lastly, the air.

The *hands* of the Surgeon and his assistants must first be carefully washed in soap and water, with a free use of the nail-brush, and afterwards thoroughly dipped in the 1 in 40 solution; and the dipping must be repeated whenever the hands have been exposed to the air unprotected by the lotion.

The *instruments* should be placed in a bath of 1 in 20 carbolic lotion, which may be diluted to 1 in 40 at the commencement of the operation by the addition of an equal quantity of boiled water. Each instrument when done with should be at once replaced in the lotion. Instruments are now frequently sterilised by means of heat. This can most conveniently be done by boiling them in water for at least a quarter of an hour before placing them in the carbolic solution; or they may be exposed to a dry heat of 120—140 °C. for an hour in a specially-constructed stove, or better to the action of superheated steam. To allow of these methods of disinfection, instruments are now made of metal only, and as far as possible in one piece. After an operation all instruments must be thoroughly scrubbed with soap and water and carefully dried. In private practice sterilisation by boiling can be easily carried out.

The *Sponges* must be prepared as before described (p. 40), and must be freshly squeezed out in 1 in 40 solution when handed to the assistant. The *ligatures* should be composed of either silk or catgut prepared as described in Chapter XIV.; or the hæmorrhage may be arrested by fore-pressure and torsion, and the use of ligatures entirely avoided.

The risk of contamination of a wound by organisms floating in the *air* was at one time undoubtedly exaggerated; it can be obviated by wetting the surface of the wound with the antiseptic lotion at intervals during the operation and well washing it out at the end. As a mode of irrigating not only the wound but the surrounding air, and the hands of the Surgeon and his

assistants, Lister invented the plan of operating under a spray of carbolic acid. The spray may be produced by a Richardson's ether-spray-apparatus filled with a solution of carbolic acid in water (1 in 40), but the steam-spray-producer is much more convenient and certain. The vessel for the carbolic acid must be filled with the 1 in 20 solution, which when mixed with the steam is reduced to about 1 in 30. The spray is undoubtedly a most efficient means of irrigation, but its routine use was founded upon an exaggerated idea of the part played by the air in contaminating wounds, and the uniformly good results obtained without employing it have led Lister to abandon its use. Furthermore, there are many positive objections to the use of the spray. It is inconvenient during the operation, wetting the Surgeon and obscuring his view, more especially if he is obliged to wear spectacles, which become quickly clouded by it; it may sometimes, in long operations, give him unpleasant symptoms of carbolic-acid poisoning, such as a general sense of illness, pain in the back, or even hæmaturia; it may depress the patient and add to shock by chilling the surface; and, lastly, the spray-apparatus is costly, difficult to keep in order, and inconveniently cumbersome to carry about in private practice.

During an operation it is convenient to have at hand a piece of linen rag soaked in an antiseptic solution, or, as it was termed by Lister, "a guard" with which to cover the whole wound during any temporary interruption in the operation, or any part of it upon which the operator is not engaged. The blankets over the parts around the surface exposed for the operation should be covered with mackintosh-sheeting, and over this towels wrung out in a 1 in 40 solution of carbolic acid should be spread, and the Surgeon should have within reach a basin of the lotion in which he can dip his hands at intervals.

In cases in which the operation-wound is complicated by the presence of old **sinuses**, such as are met with in many cases of joint-disease, these must be scraped out with a sharp spoon, and afterwards sponged with a solution of chloride of zinc (40 grains to 1 ounce). If the sinuses be numerous it is, perhaps, safer to wash the whole wound out with chloride of zinc lotion, the good effects of which were pointed out by Campbell De Morgan many years ago. Sinuses should not be injected before the operation, as there is some danger of rupturing their walls, and if the lotion should thus be injected into the cellular tissue the most extensive sloughing may result.

Reference has already been made to the important question of the drainage of wounds. It has been seen that the serous exudation can no doubt be much reduced by the uniform elastic pressure of a large cotton-wool dressing; and by perfect apposition of the surfaces no cavity can exist in the wound for the accumulation of discharges. This much-desired result cannot, however, be obtained with certainty, and more uniform success will be obtained by the use of drainage-tubes. It must also be remembered that the antiseptic applied to the raw surface increases the serous discharge during the first twenty-four hours. India-rubber tubes are, as a rule, the best, prepared and inserted in the same way as in the treatment of abscess (p. 261). One or more must be introduced in the very bottom of the wound, and the edges of the skin may then be brought together as closely as possible, a continuous suture being used if the Surgeon prefer it. The tubes must vary in size and number with the extent and nature of the wound, and must be brought to the surface at the most convenient and dependent parts. The tubes can in many cases be com-

pletely removed on the second day, without necessarily changing the whole dressing; often, however, they are needed for longer periods, and may be gradually shortened at successive dressings.

In order to avoid the necessity of removing the dressings to shorten or remove the tubes, Neuber invented absorbable tubes made from decalcified bone. Neuber's tubes were made from pieces of ox's bone drilled, and then decalcified. Macewen, who has made extensive use of absorbable tubes, prepares them much more simply, as follows: Take the tibia and femora of a fowl, scrape them clean, and place them in a 20 per cent. solution of hydrochloric acid till they are softened, then cut off the articular ends and clean out the medulla and endosteum: place them again in the acid for another day, and keep them ready for use in a 10 per cent. solution of carbolic acid in glycerine. They must be perforated in the same way as the india-rubber tubes. They act perfectly well in most cases, resisting absorption for about eight days, but they may collapse and thus fail to act, and, in some cases, they are not absorbed, and give rise to irritation. For the drainage of small wounds a few strands of catgut or horsehair will be found very efficient.

The wound having been closed with sutures, and drainage-tubes inserted, if necessary, the next step is to apply the antiseptic dressing. No organisms capable of setting up putrefaction or fermentative changes are supposed to have been left in an active state in the wound, and the small quantity of the antiseptic left between its surfaces quickly disappears, being partly absorbed and partly washed away by the serous discharge, and thus there is no source of irritation acting on the raw surfaces which could disturb the process of repair.

An **Antiseptic Dressing** should possess the following properties: 1. It must absorb the discharges readily, and, by the action of a trustworthy antiseptic agent, prevent their decomposition. 2. It must not itself act as a source of irritation by direct contact of the chemical antiseptic with the raw surfaces. 3. The antiseptic agent must be stored in the dressing in such a form that it is not too readily dissipated. 4. It must maintain rest and apposition of the surfaces. These objects may be attained by many different forms of dressing, only the more important of which can be described here.

Antiseptic dressings may be divided into two classes; first, those which, being themselves moist, prevent scabbing, or in which drying is prevented by a waterproof material covering the dressing; and, secondly, those in which the discharge is received in an absorbent material, and there allowed to dry. To this latter class belong the so-called "lasting dressings," which in many cases may be applied immediately after the infliction of the wound, and not removed, if all goes well, till healing is complete.

1. The **Carbolic Gauze Dressing** was invented by Lister, and was the first with which genuine aseptic results were obtained with any degree of certainty. The materials required are: 1st. The carbolic gauze. 2ndly. Some thick green oiled silk, coated with copal varnish, and covered with a thin layer of a mixture of dextrine and starch, so that when dipped in the carbolic lotion it may become uniformly wetted. This is called "protective oiled silk," or, shortly, the "protective." It is almost impermeable to carbolic acid, and is itself perfectly free from irritating properties, and thus, when applied to the wound, protects the edges from the direct action of the carbolic acid. 3rdly. Some thin waterproof sheeting, known in the trade as "bat-lining," or "pink pneumatic".

The dressing may be applied with or without the spray. If the spray be not used the wound should be covered with a piece of linen rag, moistened with carbolic acid lotion (1 in 40), while the dressing is being prepared. This rag is commonly termed a "guard."

The dressing should be applied thus: a small piece of the "protective" dipped in the carbolic lotion is first applied to the wound, with a hole cut through it corresponding to the mouth of the drainage-tube. Over this is placed a double layer of gauze, dipped in the carbolic lotion and squeezed as dry as possible. This has been found to give additional safety, as the carbolic gauze often picks up pieces of dirt which are not disinfected by it in its dry state. Over the wet gauze are applied several dry layers, either smooth or crumpled up according to the form of the part. The quantity of this must be proportional to the amount of discharge that is expected to flow from the cavity. It must be arranged so as to fill up any natural hollows or irregularities of the part, so that the bandages may lie smoothly and evenly over it. The superficial dressing is then applied. This is composed of eight layers of carbolic gauze, between the two most superficial of which is placed a piece of "bat-lining." The object of this is to diffuse the discharge evenly throughout the whole dressing, and to prevent its soaking through at once opposite the wound. If no "bat-lining" is available, of course any other waterproof material will act equally well. The dressing, which must extend at least six or eight inches on each side of the opening, and furthest in that direction in which the discharge is expected to drain, is secured in its position by a bandage made of the antiseptic gauze, great care being taken to secure the edges. Lastly, elastic webbing from one inch to two inches in width according to circumstances, must be applied in such a way as to keep the edges of the dressing constantly in contact with the skin during any movement of the patient. In the case of a dressing on a limb, a single turn secured by a pin at the upper and lower end of the gauze is all that is required. In other situations the Surgeon must exercise his ingenuity in applying it in such a manner as to fasten the edges of the dressing securely on the part. It must, of course, not be applied so tightly in any case as to interfere with the circulation. The introduction of a few turns of elastic webbing in the application of the dressing is an important element in the success of the treatment.

The gauze dressing thus applied acts antiseptically in two ways: 1st, mechanically, by filtering any air that may pass through it, and thus excluding dust; and 2ndly, chemically, by slowly yielding up to the decomposable fluids which soak into it a sufficient quantity of carbolic acid to prevent putrefaction. Rest of the wound is favoured by the slight rigidity of the eight layers of gauze, by the gentle pressure of the bandage, and by the comparative infrequency of the dressings.

A carbolic gauze dressing must be changed at the end of the first twenty-four hours, or sometimes even before this if the discharge be very abundant. After this it must be carefully watched, and if any discharge appear at its edge it must again be changed. The carbolic acid being very volatile at the temperature of the body, the dressing gradually loses its antiseptic properties. About the third day, although the ordinary signs of putrefaction are absent, Watson Cheyne has shown that micrococci may make their appearance, and that their presence may be accompanied by some fermentative changes in the discharges which render them sour and somewhat irritating, and in this way

primary union may be interfered with and suppuration set up. Bacteria are found only if the dressing completely fails and putrefaction sets in. It would seem that the micrococci are less easily destroyed by carbolic acid than the bacteria, and consequently, as the dressing begins to lose its carbolic acid, partly by volatilisation and partly by solution in the discharges, they make their appearance. Ogston has shown that in the treatment of abscesses the development of micrococci can be prevented by more frequent dressings, and he is of opinion that the benefit derived from this is worth the extra trouble involved in dressing more frequently. It is probable that after the third day a carbolic gauze dressing becomes too weak to kill micrococci, and that by the end of a week it can no longer be regarded as antiseptic in any sense of the word. It is doubtful if at any time it is capable of destroying the spores of a bacillus.

In changing a carbolic acid dressing the spray may be used by those who prefer it, but equal safety can be obtained by irrigating and by covering the wound with a "guard" as much as possible when the dressing is off.

The carbolic gauze dressing has been shown by experience to give most satisfactory results, probably in every way equal to those obtained by any other method at present devised; but it has several disadvantages. The gauze, from being impregnated with paraffin, is not so absorbent as many other dressings, and if badly prepared it may cake into a hard mass, and altogether fail to absorb. It is not safe to use it as a lasting dressing. It occasionally, but rarely, irritates the skin, or causes symptoms of carbolic acid poisoning. It cannot be prepared by the Surgeon himself under ordinary circumstances, it gradually loses its virtues by keeping, and it is somewhat expensive. For these reasons it is less frequently used now than it was a few years ago, its place being taken to a very great extent by the mercurial dressings, or by some form of absorbent wool.

Eucalyptus Gauze (p. 211) and **Thymol Gauze** have been substituted for the carbolic in cases in which the latter caused irritation or symptoms of poisoning. They are applied in the same way as the carbolic gauze, and when quite freshly prepared, may be relied upon to prevent putrefaction; but they quickly lose their virtue, owing to the great volatility of the antiseptic.

The application of **various antiseptic lotions on lint** is a common mode of treatment, and is often attended with very good results, but if the discharge be abundant, decomposition is very apt to occur. Carbolic acid lotion (1 in 10) may be used in this way, but it requires very frequent changing, as the acid rapidly volatilises. It is, moreover, apt to irritate the wound and to interfere with union. Boric acid lint soaked in a concentrated solution of boric acid is less irritating, but it is not a very powerful antiseptic. The addition of one-fourth part of glycerine to the lotion prevents the lint from drying, but it is rather a painful application to a raw surface.

Oil containing some antiseptic in solution is one of the most ancient forms of dressing. Lint soaked in *carbolic oil* (1 in 10), applied so as to extend for some inches round the wound, may occasionally be useful in the absence of more convenient means, but it is not a very satisfactory dressing. It is a feeble antiseptic, and is apt to stick to the wound and become dry. It should be changed at least twice a day. Lint soaked in a mixture of one part of terebene to five parts of olive oil has given satisfactory results. All these

modes of treatment involve somewhat frequent dressing, and consequently some degree of disturbance of the wound.

II. The antiseptic dressings belonging to the second group are very numerous. They have the following points in common: First, the material used is more or less elastic, and is applied in large quantity, and secured by a bandage with some firmness, so as to exert a uniform pressure on the wound. This is the principle of Guerin's cotton-wool dressing already described (p. 322). Secondly, it is absorbent—the more so the better—so that the discharges shall diffuse themselves widely through it. Thirdly, it is impregnated with some efficient chemical antiseptic, which, becoming dissolved in the discharges, prevents their putrefaction. Fourthly, the dressing is not covered with any waterproof material, free evaporation being encouraged, so that the discharges, becoming dry, may thus certainly be prevented from decomposing, and the wound may heal as under a scab. Fifthly, if the object of the dressing is attained, and the discharges are completely absorbed and dried, the dressing is not changed until the wound is healed, unless it is necessary to do so in order to remove a drainage-tube or to take out deep stitches, provided that the patient is free from pain, and that the temperature remains at or near the normal standard. If the discharge be very abundant, so as to soak through the dressing, it of course becomes necessary to take it off and to reapply it, as under such circumstances the chemical antiseptic would be washed out, and decomposition would follow.

These dressings, by the uniform pressure they exert on the wound, ensure perfect coaptation of the surfaces, and tend to limit the exudation and facilitate drainage. They maintain the most perfect rest and avoid the disturbance of frequent dressing. They efficiently prevent putrefaction and infection, first by the chemical antiseptic they contain, secondly by drying the discharges, and thirdly by filtering the dust from any air that may circulate through them.

Dressings impregnated with Perchloride of Mercury are now very extensively employed, both in Europe and America. Any absorbent substance may in this way be made into an antiseptic dressing; sawdust, ashes, sand, wool-wool (p. 209), cotton-wool, linen rags, peat, moss, tow, jute, and many other substances have thus been made use of. This is indeed one of the greatest advantages of this form of dressing, and one which makes it specially applicable to military surgery. The antiseptic can be carried in the solid form, occupies but little space, and the Surgeon can seldom be placed in such a position that he cannot find some absorbent material with which to make his dressing.

A good example of this form of dressing is that adopted by Max Schede in the Hamburg Hospital. The material he uses is dried moss (*sphagnum*). This is picked over to free it from foreign matter, and then soaked for some hours in a solution of perchloride of mercury (1 in 500). It is then taken out and squeezed as dry as possible, and put into bags made of coarse muslin or gauze, which have been similarly treated. The bags are of all shapes and sizes, and about one inch in thickness. The cushions thus made are kept ready for use in a box lined with glass, and are not allowed to become quite dry. The wound having been closed and the drainage-tubes inserted, it is first covered with a thin layer of spun-glass, taken freshly from a 1 in 1000 solution of perchloride of mercury. Over this cushions of proper size and

shape are applied, so as to press the surfaces closely together, and over all a large cushion firmly secured by a bandage, which has also been disinfected with the sublimate solution. The early discharge washes the mercury out of the spun-glass, and then forms with it a collodion-like covering to the wound. The dressing is now allowed to dry, and if all goes well it is not moved till the seventh day, when the drainage-tube is removed. A second dressing is then applied, and left on till the wound is healed. If no drainage-tube has been inserted, one dressing only is required. According to Schede, this dressing very rarely irritates the skin. In impregnating cotton-wool he adds 1 part in 10 of glycerine to the mercurial solution. This increases the absorbing power of the wool. The results of this dressing have been very satisfactory. The antiseptic used is of sufficient strength to destroy not only the ordinary bacteria of putrefaction but also the spores of bacilli.

Sublimate Wood-wool is applied in the same way as the moss. The material is sold ready prepared. It is very absorbent and elastic, and makes an excellent dressing.

The Sal Alembroth Gauze and Wool (p. 209), introduced by Lister, have been largely used, and with good results in most cases. The gauze is elastic in mass and very absorbent. The dressing is thus applied: A piece of the gauze about four layers thick is dipped in a 1 in 2000 solution of perchloride. This washes out the sal alembroth, and leaves the gauze aseptic and quite free from irritating properties. This piece of gauze squeezed as dry as possible is applied next the wound. Over this a mass of the gauze some ten or twenty layers thick is applied, and over that again the wool. The whole is secured by a bandage. The wool, containing 2 per cent. of the salt, might irritate the skin if applied directly to it. The chief fault of the dressing is that it will not deal satisfactorily with large quantities of discharge. Owing to the great solubility of the sal alembroth it is readily washed away, and thus the dressing may fail as an antiseptic. If the discharge is small in amount and dries in the dressing, the result is all that can be desired.

The Double Cyanide Gauze (p. 209) has proved to be a most efficient dressing. It appears very rarely to produce irritation, and as the salt is very little soluble in the serous discharges, the dressing retains its antiseptic properties, even though the exudation be abundant. Lister recommends that the gauze should be sprinkled in bulk with 1 in 20 carbolic lotion, and kept wrapped in a sheet of hat-lining: the double salt being a powerful inhibitory agent, but only a feeble germicide, it is desirable in this way to destroy any organisms which may have gained access to the dry material. The thickness of gauze which is applied next the wound should be thoroughly wrung out in 1 in 20 carbolic solution; over this a mass of gauze treated as above described is placed, and over this again the salicylic or sal alembroth wool. Lister has found a cream made by moistening the dry cyanide powder with 1 in 20 carbolic acid solution very useful as an application to the skin around operation wounds situated in the neighbourhood of the anus, and in other positions where contamination of the wound from the surrounding parts is likely to occur.

Salicylic Wool, Salicylic Jute and Tow, Salicylic Silk, Iodoform Wool, are all applied in the same way as Guerin's cotton-wool dressing (p. 322), from which they differ only in the presence of the chemical anti-

septic. The salicylic and iodoform wools have been extensively used at University College Hospital during the last few years with the most satisfactory results, the wounds frequently healing under a single dressing. In operations in which a prolonged discharge of small amount may be expected, as in those for carious bone, it is often convenient to apply a piece of protective oiled silk over the wound to prevent scabbing, which might hinder the escape of any pus or serous fluid.

Carded Oakum, Tenax or Marine Lint, is a cheap antiseptic dressing, but it is not adapted for direct application to a wound, as it is too irritating. It may, however, be applied over one of the absorbent dressings above mentioned in order to economise the more expensive material.

Iodoform Treatment of Wounds was first introduced in Vienna in Billroth's wards, and has been much used there, according to Mosetig v. Moorhof, with the most satisfactory results. It is thus carried out. In the case of an operation the instruments may be disinfected with carbolic acid, and the sponges washed in some weak antiseptic solution, but this is not regarded as essential. The bleeding is arrested by catgut ligatures or torsion, and the wound cleaned. The raw surfaces are then freely dusted with finely powdered iodoform, drainage-tubes are inserted, and sutures applied in the usual way. The external dressing is composed of any absorbent material, such as gauze, wool, moss, &c., which may be impregnated with iodoform; but for prevention of sepsis reliance is placed rather on the iodoform in the wound than on that in the dressing. The advantages claimed for this treatment are, that it relieves pain by the anodyne action of the iodoform, that it is simple and efficient, and that the portable nature of the antiseptic makes it applicable in military surgery and in country practice. On the other hand, the antiseptic properties of iodoform have been denied; it has been said to fail entirely in the prevention of erysipelas, and to be liable when used in this way to give rise to iodoform poisoning. That iodoform does possess powerful antiseptic properties can hardly be doubted. In open wounds with loss of substance which cannot be treated by the methods before described, such as those left after removal of the tongue or after operations on the anus and rectum, its effect in preventing putrefaction is undoubted, and there is no more efficient antiseptic application. In excision of the tongue its use has reduced the death-rate to less than half of what it was. In such cases it is invaluable; but in clean wounds which can be accurately brought together, the iodoform can only be regarded as a foreign body, the introduction of which is not necessary. If not used in too great quantity, however, it does not interfere with primary union. Mosetig v. Moorhof states that he has very rarely observed any symptoms of poisoning. When it does occur he asserts that it is almost invariably due to one of three causes: First, to the simultaneous use of carbolic acid, which he believes interferes with the elimination of the iodoform by the kidney; secondly, to the use of excessive quantities, especially in fat subjects, iodoform being soluble in fats; and thirdly, to the presence of kidney disease or fatty heart. That it fails in the prevention of erysipelas is probably true. Its unpleasant smell is also no slight disadvantage. Taking everything into consideration, it may be said that the iodoform dressing is a reliable method of treating wounds, and in many cases is the most convenient that can be adopted.

The methods of treatment here recommended are all of established utility,

but numberless others have been tried and abandoned, or are at present being tested; and probably we have not yet discovered either the best antiseptic or the best mode of dressing. The tendency of the present time is in favour of some of the forms of lasting absorbent dressing impregnated with some efficient antiseptic. The Surgeon should make himself familiar with various methods of treatment, and employ that which seems most suitable to the case. It can rarely happen in civil practice that he is so situated as not to be able to adopt some efficient antiseptic treatment provided that he has mastered the principles upon which that treatment is founded.

Inflammation of Incised Wounds.—As before pointed out, a certain degree of inflammation is a necessary part of the healing of a wound by first intention. This should, however, be strictly limited to the tissues actually injured by the instrument which produced the wound, and should be very temporary in character. The simple traumatic inflammation, although pathologically of such great importance, is clinically so slightly marked by symptoms that it is frequently ignored; and when we say that a wound is "inflamed," we mean that some cause of inflammation other than the original injury has been introduced, which is causing the process to extend beyond the area actually injured by the cutting instrument. The causes of such inflammation have already been so fully discussed that we need only recapitulate them. They are predisposing and direct. The predisposing causes are the same as those of inflammation in general (see p. 172). The most important of these for wounds are: chronic alcoholism, insufficient and improper food, Bright's disease and diabetes, scurvy, &c., and local malnutrition from disease of the arteries. The direct causes are mechanical, as friction from want of rest, tension from tight stitches or from insufficient drainage, or pressure from tight bandaging; chemical, as the persistent contact with the raw surface of an irritating antiseptic or the products of putrefaction; and lastly, the true infective poisons, as those of erysipelas, pyæmia, hospital gangrene, &c. In the vast majority of cases in which a wound "inflames," the immediate cause is the presence of putrid discharges with insufficient drainage.

When a wound becomes "inflamed," the natural slight swelling and redness of the lips become exaggerated and extend further from the edges than they should, and instead of tending to subside after the first twenty-four hours, continue to extend to the third day or even later. The serous discharge, instead of ceasing on the second day, continues to flow and may increase considerably in quantity, and gradually by the third or fourth day assumes a distinctly puriform character. Instead of the perfect painlessness of a healthy wound, there is throbbing tensive pain with acute tenderness. The temperature rises to 101—104° F. according to the size of the wound and the cause of the inflammation. In all cases the thermometer gives timely warning of the approach of this traumatic fever. The use of this instrument in surgical practice is attended with great advantage, as it often furnishes the earliest indication of the onset of some of the more serious sequelæ of wounds. The other symptoms of fever, hot skin, quick pulse, thirst, &c., are also present. In these circumstances all chance of union by the first intention is of course at an end; some or all of the sutures should immediately be removed to facilitate drainage and relieve tension, and strips of plaster may be used for support only and not for the purpose of maintaining contact of the surfaces in the hope of

obtaining union. If the wound is aseptic, which is rarely the case, the relief of tension alone may suffice to mitigate the symptoms; if the discharges are decomposing, some warm moist and antiseptic application should be used. The best of these is boric acid lint, or simple lint, three or four layers thick, moistened in a solution of boric acid, and applied as hot as the patient can bear it. The surface of the lint next the wound may be sprinkled with iodoform to render it more antiseptic. It must be covered with oiled silk and cotton-wool, and changed every four hours. A very efficient antiseptic fomentation may be made by wringing out a mass of salicylic wool in boiling water, and applying it in a similar way. Should these not be available, lint may be soaked in warm carbolic lotion (1 in 50); or a hot solution containing two grains of chloride of zinc to the ounce may be used. Simple warm-water dressings and poultices should be avoided, as they tend powerfully to encourage putrefaction. If the discharge is very abundant, the actual wound may be protected with a piece of lint dipped in carbolic oil (1 in 10), and the whole part surrounded with a mass of oakum wrung out of hot water and applied like a hot fomentation. If the wound be at all foul, the cavity must be syringed out at each dressing with some antiseptic solution, or a small quantity of iodoform may be powdered into it.

When the signs of acute inflammation have subsided, strips of lint dipped in lead lotion (Liq. Plumbi 3ss, Sp. Rect. ʒi, Aq. Oj), and applied like straps to bring the surfaces together, will be found a very useful dressing. When granulations have sprung up and suppuration has fairly set in—that is to say, by about the tenth day—the granulating surfaces may, if possible, be brought together again by plasters and bandages, with a view to their uniting by “secondary adhesion.” If this should be impossible, the raw surface becomes a “healthy granulating sore,” and must be treated in accordance with the principles that guide us in the management of ulcerated surfaces (p. 274 *et seq.*). During the period of suppuration, the patient's strength must be well supported by proper diet, and his general health carefully attended to.

Inflammation may occur at a later period of the case, owing to a failure in the drainage and the accumulation of septic matter in the cavity, or to the infection of the wound with one of the specific infective processes, as hospital gangrene, erysipelas, wound-diphtheria, &c. Under these circumstances any union that may have taken place breaks down. The symptoms and treatment of these specific inflammations will be fully described in the chapters specially devoted to them. Inflammation from accumulation of decomposing discharges must be treated by partially opening up the wound and inserting drainage-tubes.

CONTUSED AND LACERATED WOUNDS.

These are wounds attended with more or less bruising or tearing about the edges and sides, and present every possible variety in degree from a cut on the shin to the crushing and laceration of a limb by a cannon-shot. They are commonly inflicted by blunt instruments, as by stones, bludgeons, &c. Lacerations by machinery, in which parts are torn off or crushed, the bites and gorings of animals, and gun-shot injuries of all kinds, come under this denomination.

CHARACTERS.—Whatever the mode of infliction, these wounds present certain characters in common. Their lips are irregular and torn, less gaping than incised wounds, and surrounded by more or less ecchymosis. There

is usually but little hæmorrhage, and the pain is of an aching or dull character.

They differ from incised wounds in the fact that a distinct layer of tissue injured by the instrument which inflicted the wound is actually killed, and, if of any thickness, must be separated and thrown off, as a slough, before union can take place. No sharp line can, however, be drawn between the different kinds of wounds. Some wounds, which from the mode of infliction and their appearance would be classed as contused, are in reality capable of uniting by first intention, the layer of dead tissue being either microscopic or wanting. This is especially the case in vascular parts, such as the scalp and face. In other cases, a wound apparently similar may slough for a considerable distance on each side.

In consequence of the sloughy state of their lips and sides, *the majority of contused and lacerated wounds unite by the second intention.*

Contused and lacerated wounds present peculiarities according to the mode of their infliction. When they are produced by the bite of a large animal, the part injured becomes very painful, and inflames extensively: the wound being lacerated, much contused, and often penetrating deeply. It sloughs in consequence of the pressure to which it has been subjected, and of the sinking and tearing of the part by the animal. When inflicted by the tusk or horn of an animal, the wound is extensively lacerated rather than contused, and often partakes of the nature of a punctured wound.

When a part of the body is torn off, the wound presents peculiar characters: which differ, however, according as the separation is effected at the part struck or seized, or at a distance from it. In the first case—as when an arm is caught in a machine of any kind and crushed or torn off—the stump presents a ragged surface, the skin being stripped away higher than the other parts, the tendons hanging out, and the bellies of the muscles that are torn across being swollen, protruding, and apparently constricted by the lacerated integument. A most important condition in such wounds is the state of the vessels: these are separated lower down than the other parts, for, being elastic, they elongate and pull out before they give way. There may be no hæmorrhage, because the inner and middle coats of the artery, breaking off short, retract and contract to a small aperture, and allow the external coat to be dragged down and twisted over them, in such a way as to offer a complete barrier to the escape of blood. The bone is crushed off at the end of the conical stump, of which it forms the apex, and is often split up to the next joint above.

Occasionally, when parts are pulled off, they are separated at a distance from the point seized. Thus, fingers that have been torn off by machinery have their extensor and flexor tendons separated higher up, at their junction with the belly of the muscle, and not at the part seized; the tendon being drawn out of its sheath, and hanging on to the separated end in a ribbon-like manner.

This peculiar tearing away of the tendon from its attachment to the muscle and not across the line of laceration of the limb, was described by several writers in the *Mémoires of the Academy of Surgery of Paris* in the middle of the last century, and the accompanying figures, 100, 101, taken from Mornot's paper, illustrate well this very singular injury. In railway accidents, when a train has passed over a limb without completely separating it, the muscles may be found detached from their origins.

Progress.—In the progress of a contused or lacerated wound there are two distinct periods: 1, the separation of the slough produced by the contusion; 2, the repair by granulation of the cavity left. The process by which a slough is separated has already been described on p. 270, and that of repair by granulation on p. 293.

The **Extent of the Slough** depends not only upon the extent and severity, but also upon the situation, of the injury. If the parts around the wound be much bruised, superficial sloughing to a great extent may occur: if the wound be deep though not extensive, there will always be danger of deep suppuration and burrowing of matter, leading to troublesome sloughing, and in

Fig. 100. Ring Finger torn off, with deep Flexor Tendon.

Fig. 101. Thumb torn off, with Tendon attached.

some cases to secondary hæmorrhage. Those wounds that are situated immediately over bony points—as the shin and elbow—are especially tedious, as the slough frequently implicates the fasciæ, and therefore separates slowly. The scalp, owing to its great vascularity, has less tendency to slough than any other part of the cutaneous surface. In all cases of contused and lacerated wounds, in which sloughing and suppuration follow the injury, there is a greater liability to the supervention of infective inflammations than in clean-cut incised wounds. In most contused wounds the extent of the slough is, to a certain extent, influenced by treatment. On each side of the wound, beyond the layer of tissue actually killed, there is an area, frequently of considerable extent, in which the tissues are damaged and hovering between life and death, and any additional irritation will suffice to extinguish the remains

of vitality. Thus, if such a wound be tightly sewn up, the tension of the stitches will inevitably cause sloughing in the whole doubtful area. The irritation of decomposing discharges is another most potent cause of extension of the area of death, and in fact, it is in such wounds, much more than in clean-cut incisions, that the immense benefit of some form of antiseptic treatment is most clearly recognised. In primary amputations for contused and lacerated wounds it frequently happens that the incisions pass through this doubtful area, and the extra injury thus done determines the death of the part, even though, at the time, it may have appeared to be uninjured.

The chief danger to be apprehended in wounds of this description is the supervention of **Gangrene**, which may occur in one of three ways :—

1. In some cases the violence done to the part is so great as directly to kill its whole substance. Thus, if a limb be crushed to pulp by machinery, or by the passage of a heavy waggon over it, the part may speedily become gangrenous. This is a local traumatic mortification, evincing no disposition to spread beyond the part injured, but being bounded by a line of demarcation along which it will separate. It is not always easy to distinguish this direct form of gangrene from such discoloration and disorganisation of a limb as are still compatible with life. In all cases of doubt the Surgeon must wait, and a very short time—a few hours—will be sufficient to declare whether the vitality of the part can be maintained or not. In cases of great doubt an incision might be made into the part, and the true state of things thus ascertained; but this should not be done if it can possibly be avoided, and if undertaken the most rigid antiseptic treatment should be adopted, as the decomposition of the extravasated blood in the tissues of the bruised part would inevitably extinguish such vitality as remained. In many cases it is a good plan to disinfect the part carefully, dress it antiseptically, and wait for the line of demarcation between the dead and living parts to form before undertaking any operation.

2. The injury may damage the great vessels of a limb to such an extent as to interrupt the circulation; gangrene being thus induced in the parts supplied by them. This form of gangrene we shall have occasion to treat of when speaking of Injuries of the Arteries.

3. The true "spreading gangrene," the most fatal variety of mortification, is most commonly the result of contused or lacerated wounds. This is a most acute infective inflammation, terminating rapidly in gangrene, and will be described with the other infective processes occurring in wounds.

TREATMENT OF CONTUSED AND LACERATED WOUNDS.—In the treatment of the slighter form of these injuries, we must bear in mind the occurrence of the two distinct periods: 1, that of the separation of the sloughs; and 2, that of granulation. There is also in all injuries of this description a special tendency to the occurrence of erysipelas and allied diseases.

Care must be taken to clean the parts thoroughly from foreign bodies that are frequently impacted or ground into them. However contused and torn a flap of skin may be, it should never be removed, provided it maintain any attachment to the neighbouring tissues, but should be replaced on the chance of its vitality being preserved. If it live, as it will often do, especially about the scalp and face, under apparently the most discouraging circumstances, much will be gained; if it slough, no harm can result from the attempt to preserve it. There are cases on record in which parts that have been even

completely separated have become attached, by being immediately reapplied to the surface from which they had been torn or cut. Whether or not this be actually the case in contused or lacerated wounds, it is at all events certain that a very small tongue of skin is sufficient to maintain the vitality of a part. This we see exemplified in the operation for the restoration of a lost nose; and cases have occurred to me in which the nose, retained only by a portion of one ala, has readily united on being replaced; so likewise, in bad cases of compound dislocation of the fingers, the part has been saved, though merely attached by a narrow bridge of skin. After a part has been replaced in this way, it should be retained *in situ* by a few points of interrupted suture, and dressed with boric acid ointment spread on thin muslin, or some other unirritating antiseptic application. In lacerated wounds opening into the mouth or nose a piece of lint soaked in collodion may be applied externally, as there will be ample drainage from the internal aspect of the wound. The sutures in these cases must be left in for a somewhat longer time than usual, until good union has resulted. The hæmorrhage, as before mentioned, is as a rule easily controlled; position, application of cold, and the subsequent bandaging, being sufficient in the majority of cases. When, however, the blood is bright-coloured and continues to drip from the wound, a vessel of some size has been divided: this should be searched for, and secured by torsion or ligature.

Ordinary cases of contused or lacerated wounds, whether superficially extensive or deep, are best treated on exactly the same principles as incised wounds. Although we can rarely hope for union by the first intention, *rest* is necessary to favour such union as may occur, and to relieve the patient from pain; *drainage* requires special attention, as the injury being more severe, the early exudation from the wound will be more abundant; and the *prevention of decomposition* becomes of the greatest importance, as the irritation of putrid matter might extinguish the vitality in tissues which would otherwise have recovered. In treating such wounds exactly the same proceedings must be adopted as in an accidental incised wound (p. 315 *et seq.*), but greater care is necessary in cleaning the wound with the lotion on account of its irregular nature. If there is no chance of union at any part, it is better not to insert sutures: for, as it must heal by granulation after the separation of the sloughs, nothing can be gained by their use, and they may seriously impede the drainage. There is no class of wounds in which the benefits of antiseptic treatment are more marked than in these. Under its use the sloughs may separate with scarcely any suppuration, and the inflammation accompanying the process may not extend a tenth of an inch beyond the dead tissue; and all this may occur without any general febrile disturbance. In contused and lacerated wounds of the hand or foot, in which the parts are often extremely dry, it is safer to put the limb in a bath of carbolic acid lotion (1 in 40) for about a quarter of an hour before applying the dressing in order to ensure thorough asepticity.

Should the antiseptic dressing fail, or should the case not be seen till decomposition has commenced, *Disinfectants* must be freely used. The wounds must be washed or syringed out several times a day with weak solutions of perchloride of mercury, 1 in 5000, chloride of zinc, permanganate of potash, or carbolic acid. In this way sloughs and decomposing pus may be removed, and the tendency to local inflammation of a spreading character,

and to the development of pyæmia, averted. There is no more fertile cause of these disastrous effects than the retention of fætid decomposing pus in the areolar tissue of a contused wound. The separation of the sloughs must be facilitated by the application of warmth and moisture, which serves also to subdue local inflammation. Boric acid lint, moistened with hot boric lotion and covered with oiled silk and cotton-wool, is one of the best of all applications. It is most efficient, easily applied, and perfectly clean. If the wound becomes foul, the surface may be sprinkled with iodoform in crystals. Carded oakum, moistened in hot water and covered with oiled silk, answers the purpose tolerably well; it is cheap and antiseptic, but dirties the skin. Linseed meal poultices should always be avoided; they encourage putrefaction and greatly increase the suppuration, the evil they do in this way more than counterbalancing any comfort the patient may experience from their application.

About the period at which the slough begins to be loosened, there is danger of the occurrence of **hæmorrhage** if a large artery have been implicated in the injury. When hæmorrhage occurs in this way, it usually sets in from the sixth to the twelfth day, and may be speedily fatal; the treatment should be the same as that to be hereafter described for secondary hæmorrhage after ligation of an artery in its continuity. After the sloughs have separated, an ulcer is left, which must be treated on general principles.

Amputation. In the more severe cases of contused or lacerated wounds, any attempt to save the part may be hopeless, and the patient's only chance lies in *amputation*. In determining the expediency of operation, two questions present themselves; 1, the nature of the cases in which amputation should be performed; and, 2, the time at which it should be done, whether immediately after the infliction of the injury, or subsequently.

It is difficult to lay down more than very general rules as to the *kind of cases that require amputation*, much depending on the age, constitution, and previous habits of the patient. In any case the Surgeon should be careful not to condemn a limb which there seems to be a fair chance of saving.

As a general rule, severe injuries are more readily recovered from in the young than in the old, their vitality being greater, and their tendency to consecutive diseases less. Much will depend upon the habits of the patient, or upon the existence of visceral disease at the time of the injury. In persons who have been free livers, and who have that peculiar irritability of system conjoined with deficient power commonly observed in such subjects, and more especially if there be disease of the liver or kidneys, contused and lacerated wounds are apt to be followed by the worst forms of erysipelas and gangrenous cellulitis, and thus to be speedily fatal. Injuries of the upper extremity are less serious than those of the lower, its supply of blood being proportionately greater. In some contused wounds of the arm and hand, as in bad lacerations with fracture about the shoulder, elbow, or metacarpus, resection of the injured part may be performed instead of amputation of the limb.

Though there must be in many cases a doubt as to the necessity of amputation, there are certain conditions in which the Surgeon need never hesitate to perform this operation, as the only chance of saving the patient's life. The following are cases in which the limb should be amputated, either with the view of preventing the occurrence of gangrene, or in order to remove a mortified part, and thus save the life of the patient at the expense of the injured limb:

1. If a limb have been torn off by machinery, carried away by a cannon-shot, or cut off by the passage of a railway-train over it, the irregular and conical stump should be amputated.

2. If the whole thickness of a limb—the soft parts and the bones—be thoroughly disorganised and crushed, it must be removed.

3. If the soft parts be extensively stripped from the bones, though these be entire, so much sloughing will ensue as to leave a useless limb, and amputation should be performed. It is in these cases that it is often especially difficult to estimate the amount of injury that cannot be recovered from, this depending much upon the age and constitution of the patient. In such cases the life may be lost in trying to save the limb. I have more than once had reason to regret having attempted to save limbs injured in this way; and I believe that, if the skin of the lower extremity be extensively torn down and the muscles much lacerated, so as to slough away, there is but little chance for the patient—unless he be young, and of a remarkably sound constitution—except in amputation. In the upper extremity it is different; there, recovery may take place under the most adverse circumstances. In all parts the dangers of attempting to save a limb have been greatly lessened by the antiseptic treatment. If decomposition of the sloughing tissues can be prevented, there will be little fever and but slight local inflammation, and the risk of pyæmia and erysipelas or other infective processes is scarcely appreciable. Supposing the attempt to save a useful limb to fail, if the antiseptic treatment is successful the chances of recovery are in no way impaired by the delay in amputating.

4. So also, if the knee be largely opened, with laceration of the soft parts and perhaps fracture of the contiguous bones, the limb must be amputated. Corresponding injuries of the ankle, shoulder, and elbow joints may, as has already been stated, admit of resection rather than amputation. In these cases also, the antiseptic treatment is an important aid in saving a limb, for if decomposition can be prevented, the mere fact that a joint is opened adds but little to the gravity of the case.

5. Bad crushes of the foot have a great tendency to run into gangrene, and hence require amputation. In the hand, on the contrary, very extensive injuries are often recovered from without this operation being necessary; and in many cases partial resection may be substituted for it.

6. In those cases in which a large artery, as the femoral, is lacerated at the same time that the soft parts are extensively injured, and the bone fractured, amputation is required in order to prevent the occurrence of gangrene. In the non-local form of traumatic gangrene, in which the disease is confined to the part directly crushed and injured, no good can come of delay, and amputation should be performed as soon as mortification has declared itself; and the limb must be removed at a sufficient distance from the seat of mischief. When the mortification results indirectly from injury of the vessels, the limb should also be immediately removed in a line with the wound, unless this be too high up; even the most favourable point must be chosen, as will hereafter be explained. Amputation in these circumstances is by no means a very unfavourable operation, and it is one that I have several times successfully performed, provided it be done sufficiently early, before the constitution becomes poisoned by the absorption of septic matters from the gangrenous tissues. It is scarcely necessary to warn the Surgeon to be certain of the existence of gangrene before he

operates; and also that it be not a mere limited slough, but sufficiently extensive to jeopardise the patient's life.

7. In cases in which spreading gangrene attacks the wound early, amputation is the only hope of saving the patient.

The question as to the *period* at which amputation should be performed in contused wounds from gun-shot will be considered later on. It may be generally stated, that the sooner a condemned limb is taken off, the less is the suffering, and the better the chance of recovery of the patient; and that, consequently, primary amputation should be practised in these cases. By reference to the tables on pp. 89, 90, it will be seen that, although the average mortality for all primary operations is less than the average mortality for all secondary operations, yet primary amputation through the thigh is more fatal than secondary amputation in the same region. Notwithstanding this, it is absolutely necessary in many cases to remove the injured limb within the first twenty-four hours. The higher rate of mortality of primary thigh-amputations may be due chiefly to the greater severity of the injuries that manifestly require immediate operation than of those in which it is thought justifiable to attempt to save a limb; and certainly, of the two alternatives—of leaving a badly crushed and mangled limb until suppuration has set in, and thus exposing the patient to all the risks of gangrene, erysipelas, pyæmia, &c., or removing it at once—the latter is the one attended with least danger to the patient.

A limb is sometimes so hopelessly crushed that any attempt at its preservation must be useless; whilst at the same time the patient is so severely injured internally, or is so prostrated by shock, that amputation as a formal operation would be as useless as it would be unjustifiable, the patient having at most but a few hours to live. In these circumstances the best thing that can be done is to put on a tourniquet, partly to check hæmorrhage, and partly to restrain the painful quivering of the muscles, and to wrap up the maimed limb. Should the limb have been nearly detached—merely hanging on by shreds of the lacerated muscles—these may be divided, and its removal thus effected without additional shock or suffering.

BRUISE-BURN.—This is a peculiar injury occasioned by rapid and severe friction of the surface of the body, so that the skin becomes abraded and the subjacent tissues somewhat contused. It is not unfrequently produced in the manufacturing districts, by the surface of the body coming into contact with straps or portions of machinery in rapid motion. It has also been known to occur in consequence of a person slipping and sliding rapidly down a long and steep Alpine snow-slope. In this injury the integument is, as it were, ground off, and the areolar and aponeurotic structures converted into an eschar.

The *Treatment* presents nothing special, but should be conducted on ordinary principles. The separation of the eschars must be facilitated by moist antiseptic applications, and the resulting sores will heal by granulation.

STABB AND PUNCTURED WOUNDS.

These wounds, made by narrow sharp-pointed instruments, vary greatly in extent, from the prick of a needle in the finger to a sword-thrust through the body. Not unfrequently punctured wounds are somewhat contused, being made by a triangular or wedge-like weapon, as a bayonet or lance-blade.

When deep, they are of a most dangerous character—wounding blood-vessels, traversing the great cavities, and injuring the contained viscera. A punctured wound is extremely difficult to drain, the external orifice being very small in proportion to the area of the surface. Thus, if a narrow weapon half an inch in width were thrust into the thigh for a depth of six inches, the area of the two surfaces of the wound would be six square inches, while the external opening would be only half an inch in length. The small external opening is easily choked by a clot of blood, and is frequently injudiciously closed by the Surgeon. The whole track becomes distended with the blood or serous exudation, and unless means are taken to prevent it, decomposition sets in, followed by inflammation and suppuration extending deeply into the injured part. In consequence of this, combined with the insufficient exit for the discharges, the pus may burrow deeply, large collections of septic matter may form, and severe constitutional disturbance is the necessary result.

TREATMENT.—In the treatment of punctured wounds, the principal points are to arrest the hæmorrhage, and to facilitate union.

The hæmorrhage must be arrested by pressure properly applied by means of compresses or pads, so as to approximate the sides of the puncture; by the application of cold; or by cutting down on the injured vessel if it be a large one, and ligaturing above and below the perforation in it.

In many cases of severe punctured wound suppuration and union by second intention will take place in consequence of the great difficulty in drainage. In order to obtain early union, the cavity should be washed out with carbolic acid lotion (1 in 40) or some other antiseptic, by means of an india-rubber tube on the end of a syringe. Care must be taken that there is plenty of room for the fluid injected to flow out rapidly, otherwise the spaces of the areolar tissue will become widely distended with the antiseptic solution; all superfluous lotion is then squeezed out, and a drainage-tube inserted deeply into the wound. This may be considerably shortened after twenty-four hours, and gradually diminished day by day till it can be safely removed. The external application should be one of the forms of absorbent antiseptic dressing. On no account should a punctured wound be closed by collodion or any other occlusive application. The small size of the external opening is apt to make the Surgeon forget the real extent of the injury. As the tube is shortened, the coalescence of the sides of the wound may be encouraged by properly applied compresses and bandages. The deep inflammation that so often follows these wounds is due solely to insufficient drainage and decomposition, and no treatment but the prevention of these conditions will exclude it. In former days, when duels with the small sword were of frequent occurrence, persons called "suckers," who were often the drummers of a regiment, were employed to attend the wounded combatants. Their treatment, which was conducted with a certain degree of mystery, consisted in sucking the wound till all blood ceased to flow, and then applying a pellet of chewed paper or a piece of wet linen to the orifice; in this way it would appear that many sword-thrusts traversing the limbs were healed in a few days. The process of suction cleared the wound thoroughly of all blood, and, drawing the sides into close apposition, placed the parts in the most favourable condition possible for union by primary adhesion. This practice might, perhaps, in many cases be advantageously imitated in the present day by means of a cupping-glass and syringe.

Amongst the varieties of punctured wounds that are most commonly met with in ordinary practice are those which are occasioned by needles penetrating into, and breaking off in the body. These accidents occur chiefly in the fingers and feet, and about the nates; and, though trivial, are often extremely troublesome, both to the Surgeon and to the patient. When the Surgeon is called shortly after the occurrence of the accident, he must endeavour to remove the fragment left behind, by cutting down upon it. In doing this he will be guided by the situation of the puncture, and by the seat of the pain, and sometimes by feeling the point projecting under the skin. In many cases this is a sufficiently simple proceeding; in others, however, a deep and troublesome dissection may be required, especially when the fragment of needle gets into or under the sheath of a tendon. I have had occasion to undertake somewhat troublesome dissections for the removal of needles; in one case between the biceps tendon and the brachial artery, and in another in close proximity to the ulnar artery in the wrist. For the purpose of extracting needles, thorns, splinters of wood, and other foreign bodies of small size and pointed shape lying in narrow wounds, forceps with very fine but strong and

Fig. 102. Indian Arrow penetrating temporal bone. Medical Department, United States Army.

well-serrated points will be found useful. One of the most dangerous situations for a needle to penetrate is the anterior part of the knee-joint, lodging in the head of the tibia or in the patella, and breaking off short. In such cases the fragment should be dissected out at once, the strictest antiseptic precautions being adopted to prevent inflammation of the joint. The limb must then be fixed on a splint. I have known the most acute suppuration of the knee ensue in consequence of a portion of needle having been allowed to remain embedded in the joint. The patient's life was in imminent peril, but recovery ultimately took place with ankylosis of the joint.

The movements of the part in which the needle is lodged tend to make it travel in the direction of its point, and consequently in many cases if it has been lodged for some days the Surgeon will fail in his endeavours to extract it. Unless, therefore, the indications of its presence be very clear, I think the wiser course would be to leave it undisturbed, and to trust to nature for its expulsion, as it can seldom be found when sought for, and, indeed, may not exist, although supposed to be present. The following plan of ascertaining whether a portion of needle be really impacted has been suggested by Marshall

and successfully carried into practice by Littlewood of Leeds. A powerful magnet is to be held upon the part for a quarter of an hour, so as to magnetize the fragment; a finely hung polarized needle should then be suspended over it, when, if any iron is present, deflection will ensue.

When a fish-hook, crochet-needle, or other barbed instrument has been run into the flesh, no attempt should be made to withdraw it through the aperture by which it entered, but the point should be pushed on so as to emerge through the skin, the shank then divided with pliers, and the barbed end drawn out.

ARROW-WOUNDS occasionally fall under the observation of the military or colonial Surgeon as the result of injuries received in conflict with barbarous races. They differ only in one essential respect from penetrating punctured wounds made by knife-stabs and sword-thrusts, viz., that the arrow-head will remain impacted in the tissues it has penetrated (Fig. 102). The force with which an arrow may be shot is well illustrated in the accompanying figures taken from preparations in the Army Museum at Washington. The arrow shot from the bow of a North American Indian has been known to traverse the body of a buffalo and penetrate the under surface of its scapula, as shown by a preparation in the same Museum.

The extraction of an arrow is usually attended with little difficulty. But if barbed, or if the shaft becomes detached from the head, special precautions have to be taken. With the view of safely effecting its removal, the "snare" figured below (Fig. 104) have been devised.

Arrow-Heads.

CHAPTER X.

GUN-SHOT WOUNDS.

GUN-SHOT wounds, though comparatively rare in civil practice in this country, are yet sufficiently frequent to render an acquaintance with them indispensable to the general Surgeon. To the military Surgeon the study of them is necessarily one of the greatest importance; and to him I would specially recommend the perusal of the works of Longmore, Stromeyer, Esmaich, and Fischer, who have had unusual opportunities of studying these injuries on the field of battle. The works of Guthrie, Hennen, and Larrey, whose experience was gained in the wars in the early part of the present century, are well worthy of study, and much that is interesting will be found also in the writings of Ambrose Paré, Wiseman, and John Hunter.

In the following observations I shall confine myself to such a general discussion of the subject as may be useful to the civil Surgeon.

Gun-shot injuries constitute a species of contused and lacerated wounds, often partaking also of the nature of punctured wounds in the disproportion between the subcutaneous mischief and the external aperture. They are characterized in many cases by the extensive injury inflicted on the tissues, both superficial and deep, in consequence of which the wounds may prove immediately or rapidly fatal. If the sufferer survive the immediate effects of the injury, acute inflammation with much pain and tension, deep-seated suppuration, profuse discharge, and other serious and very protracted after-consequences, are apt to supervene. These peculiarities have at different times been attributed to the parts being burnt by the ball, to the poisonous nature of projectiles, to the generation of electricity in the bullet during its passage through the air, or by its friction against the barrel. All these opinions, however, have been shown to be erroneous; and every peculiarity of these injuries can be accounted for by the bluntness of the missile, the force with which it is driven, and by the insufficient exit for the decomposing discharges that necessarily accumulate in the track of the bullet, unless septic processes can be prevented by the efficient use of antiseptics. John Bell has pathily remarked, "there is a peculiarity, but no mystery, in gun-shot wounds."

CHARACTERS.—Gun-shot wounds vary greatly according to the nature of the Projectiles, the force with which they are driven, and the direction in which they strike.

Nature and Force of Projectile.—Injuries of a serious character may be inflicted by *weapons charged only with powder*. These may arise from the mere concussion of the explosion; thus a pistol charged with powder, and discharged with the muzzle resting against the chest of a man, has been known to kill by concussing the heart. In other cases, a portion of the unexploded powder may be driven into the skin by that which is exploded behind it. In this way, very disfiguring marks are sometimes made on the face by the powder lodging in the skin. The force of the explosion will sometimes

produce serious lacerations. Suicides occasionally forget to put a bullet into the pistol, and firing into their mouths, blow open the cheeks, and injure the pharynx and glottis by the explosive force. Some years ago, a man was brought to University College Hospital, who had discharged some powder from the tube of an Italian iron into his mouth, and he died in consequence of the injuries he received. In another case, a man died, on the fifth day after firing a pistol into his mouth, of asphyxia, occasioned by sloughing of the pharynx and inflammation of the glottis and larynx, consequent on the scorch of the explosion.

Wadding and Soft Materials, as pieces of clothing, will occasionally inflict serious wounds by the force with which they are driven into the body. These injuries often happen on the stage, at reviews, fairs, &c. Taylor relates several instances of the kind:—one of a girl killed by a gun charged with paper pellets; also, one of a man who was killed by a kid glove fired from a blunderbuss. Dupuytren mentions a case in which a fowling-piece loaded with powder and a paper wad, and fired at a distance of two or three feet, killed a man by piercing the abdomen with a round hole.

Small Shot often inflict serious injuries, and these are most commonly met with in civil practice. If the person wounded be within a few feet of the muzzle of the gun, a terribly lacerated wound, even worse than that occasioned by a bullet, will be inflicted; for the shot, not being scattered, are driven through the body in a compact mass, and tear the tissues to a great extent. The compactness of a charge of shot when striking close to the muzzle of the gun may be very remarkable, making a wound like that of a bullet. A lad was admitted into University College Hospital under my care, who had accidentally shot himself. The whole charge had passed from before backwards between the skin of the inner side of the arm and the brachial vessels and the accompanying nerves, leaving a bridge of skin about three inches in width and the vessels and nerves uninjured, the triceps, however, being torn. The patient made an excellent recovery.

When shot scatter as they fly, they produce at a greater distance a less serious injury, usually lodging in the subcutaneous areolar tissue, where they may remain permanently without causing any trouble; or they may give rise to suppuration. Penetrating an important part, shot may cause serious or fatal results; thus, a single shot penetrating the eyeball will destroy vision; or, lodging in the heart or in the femoral vein or other large vessel, may give rise to rapidly fatal results. A patient was once brought to University College Hospital, who had fired a pocket-pistol loaded with small shot into his mouth; after death, the shot were found deeply lodged in the vertebral column.

Splinters of metal, wood, or stone, carried by the force of an explosion, as in blasting and mining operations, may inflict grave injuries. These latter admit perhaps the worst forms of injury from bodies propelled by explosive force that are met with in civil practice. In siege operations much injury also is often inflicted by the splinters from parapets, or by the forcible chrowing up of gravel and small stones by the explosion of shells. In naval actions, too, the force with which splinters of wood are driven, when struck and scattered by cannon-shot, is often so great as to inflict the most serious and even fatal mischief. A particular form of injury, formerly common in civil practice, was a wound of the eyeball by the splintering of faulty percussion-

cups. Wounds of the face and other parts by the splashes or splinters of bullets from the surface of targets, are of common occurrence among marksmen at rifle-ranges.

Slugs are irregular bits of lead of no definite form or size. They produce wounds more ragged than small shot, but, unless fired at very short range, they seldom penetrate deeply. The experience of the Ashantee War, in which the natives used slugs almost exclusively, showed that the proportion of severe to slight wounds was very small, the projectile not having sufficient power to break a large bone.

Bullets occasion more serious wounds, lacerating soft parts, fracturing and crushing bones, tearing asunder vessels and nerves, perforating the viscera and occasionally cutting off parts, as a finger, the nose, or an ear.

The introduction of rifled fire-arms into warfare greatly increased the destructive effects of bullets. On the bones especially, the modern *conico-cylindrical bullet* often produces the most destructive effects: not only comminuting the part struck, but often by its wedge-like action splitting up the shaft of the bone in fissures many inches long, leading into contiguous joints (Fig. 105).

The bullet of the new Lee-Metford magazine rifle is small in diameter, and has a very high velocity. Thus the diameter of the Snider bullet is 0.577 in., that of the Martini 0.45 in., and that of the Lee-Metford 0.303 in., whilst the muzzle velocities are 1240, 1315, and 1800 feet per second respectively. The outer sheath of the new projectile is composed of a very hard combination of copper and nickel, which prevents the breaking-up of the bullet at the moment of impaction, and thus may tend to diminish the almost

"explosive" effects of the old lead bullets.

Direction.—In the majority of cases, a bullet traverses the part struck, and the wound has two apertures, one of entry, the other of exit; occasionally it

happens, however, that in consequence of the ball being spent, or of the oblique direction with which the ball strikes the part, it rebounds or glances off, leaving merely a contusion or dent. In other cases there is only one aperture; and here the bullet, partly spent, has probably lodged in the soft tissues, or in a bone, or in one of the cavities of the body. It sometimes happens, however, that the ball drops out through the aperture at which it entered, as when a spent ball strikes a rib; or that it carries a pouch of clothing before it, which enables the Surgeon to withdraw it. One

Fig. 105.—Perforation of Right Femur by bullet. Lengthened and splitting of Bone. (United States Army Museum.)

Fig. 106.—Rifle bullets. 1, Snider; 2, Martini-Henry; 3, Lee-Metford.

bullet may make even more than two apertures; thus a round ball has been known to split against the sharp edge of the tibia, and to have one aperture of entry and two of exit; or it may pass through both thighs or both calves,

and thus occasion four apertures; and cases have been recorded in which five wounds even have been made in the same person by one bullet.

The direction of the openings is often of importance from a medico-legal as well as from a surgical point of view. Thus, Sir Astley Cooper, by attending to this point in a case of murder, ascertained that the fatal shot must have been fired by a left-handed man; and this led to the detection of the criminal. These apertures, though usually opposite to one another when a ball passes right through a part, are not always so, the bullet being deflected by the bones, or by the elasticity of the skin, so that the two apertures do not correspond. Thus a spherical bullet has been known to strike a rib and then to be deflected, running under the skin to the opposite side of the body; again, striking one temple, a bullet has been carried under the scalp to the other side of the head, where it has passed out; thus it might appear that important cavities had been penetrated, when in reality they had not been wounded.

The **Apertures of Entry and of Exit**, made by a bullet, deserve attentive consideration. With the *round-bullet* projected at a comparatively low velocity, the difference in the two apertures was usually very obvious, and is well shewn in Figs. 107 and 108. The aperture of entry was small, circular in shape, less than the diameter of the ball in breadth, the edges being inverted and echymosed. The aperture of exit was commonly large, somewhat everted, and irregular, admitting two or even three fingers freely.

Fig. 107. Gun-shot Wound. Aperture of Entry.

Fig. 108. Gun-shot Wound. Aperture of Exit.

Of the various explanations which have been suggested for these differences in the character of the apertures, that given by Guthrie is undoubtedly the most important. The loss of momentum sustained by the bullet as it traverses the tissues is viewed by Guthrie as the chief factor in determining the character of the aperture of exit, and it is obvious that the loss of momentum will vary according to the velocity of the bullet at the moment when it enters the tissues, and according to the resistance with which it meets. It must also be remembered that the aperture of entry is made solely by the bullet, whilst the aperture of exit is made by it, plus the debris that it carries along with it; and further that the skin at the point of attack is supported by the tissues beneath it, whereas at the place of exit, the skin is unsupported. This is exactly what happens if we drive a nail through a board. If supported by another piece of wood, the apertures on the two sides are even and of the same size. If unsupported, the aperture on the distant side—that of exit, in fact—will be splintered, irregular in shape, and larger than that of entry.

The sloughing which occurs around the apertures is usually more extensive around that of entry than that of exit, so that the former may, at a later stage, become larger than the latter. I saw this well exemplified in the case of a young man shot through the neck with a pistol-ball in a duel. The aperture of entry, which was at first the smaller, appeared on the second day the larger in consequence of the extrusion of a black slough; though it continued more regular in shape than that of exit.

The wounds produced by *conical bullets* may present characters resembling in general those above described, but the small size of those now used and their high rates of velocity would seem materially to modify the character of the lesions produced by them. Surg.-Capt. Perry Marsh has recorded the case of a labourer who was accidentally wounded in the thigh by the conical bullet of a Lee-Metford rifle fired at a distance of 2,560 yards. The entry wound on the front of the thigh measured $\frac{3}{8}$ in. by $\frac{1}{8}$ in.; whilst the aperture of exit behind was a "clean-cut transverse slit," $\frac{1}{8}$ in. in length. Healing took place by first intention, and on examination after the patient's death from acute bronchitis on the 54th day, the track of the bullet could not be traced. Other cases lately recorded shew that the apertures of entry and exit may be identical in character. At short ranges, however, great destruction of the bones and soft tissues appears to be produced. The experiments made in France by Delorme and Chavane with the Lebel and Gras rifles shew that under these circumstances muscles are pulped and bones extensively fissured.

Fragments of **Shell**, if of large size, inflict the most terrible wounds met with in military practice, tearing off whole limbs, or great masses of flesh, and splintering the bones in all directions. At the battle of Sedan, after the Germans had shelled a crowded mass of French troops, the ground was described as covered with "heaps of flesh and rags." A small fragment may either become lodged, or make its way out, the aperture of entry being somewhat incised, though very irregular, and the aperture of exit large and ragged.

The old round **Cannon-Ball**, in fact, solid shot of all kinds, are now quite abandoned in war, being replaced by shells fired from rifled cannon. The old cannon-balls inflicted two kinds of injury. Sometimes they contused a part deeply without destroying the integrity of the skin, the ball being "spent," and striking obliquely. In such cases the skin, owing to its elasticity, remained unorn, though all the subjacent textures—bones, muscles, and vessels—might be crushed into a pulp, if a limb were struck; or if the trunk itself were injured, the vertebral column and lumbar muscles might be disorganized, and the liver, kidneys, spleen, stomach, and intestines ruptured. These injuries at one time erroneously attributed to the action of the current of air set in motion by the ball, were known by the name of "*wind-contusions*." In some of these contusions, gangrene of the limb set in, apparently from the rupture of the principal vessels. Cannon-shot more commonly carried away the whole thickness of a part, shattering a limb, tearing off the thick and fleshy parts of thigh, calf, or shoulder; or they inflicted the most fearful injuries by smashing the trunk and head.

SYMPTOMS.—The **Pain** in gun-shot injuries varies greatly. It is most severe when a bone is fractured, or a large cavity penetrated; when soft structures alone are injured, a dull and heavy sensation is experienced, which has often been compared to that occasioned by a blow with a stick. In many

cases, however, the sufferer is not aware that he is shot till he is told of it. I have known a person, shot in the leg by a pistol-ball, unaware that he was wounded till told that his leg was bleeding. This is especially apt to happen when the mind is actively engaged, as in the heat of battle. Hennen has known a limb carried off or smashed to pieces by a cannon-shot, without the sufferer being conscious of it. Macleod relates the case of an officer who, in the Crimea, had both legs carried away, and who was not aware of the injury till he tried to rise. Heine records a case in which a soldier ran a thorn into his foot at the same time that he received a flesh wound in the arm; he began to pull out the thorn and did not notice the arm wound until a comrade called his attention to the blood.

In gun-shot injuries, **Shock** is always very marked when parts of importance, as the head, chest and abdomen, or large joints, as the knee, are opened: and its severity is indicative of the amount of mischief inflicted. Thus, if a bullet appear to have traversed the chest, but in reality has been deflected under the skin, the comparative absence of shock will serve, to a certain extent, to prove that visceral mischief has not been inflicted. In some cases the shock alone appears sufficient to kill; thus, a man shot by a pistol-bullet, which traversed the distended stomach, died in a few seconds from shock, there being no bleeding of importance, or other discernible cause of immediate death (Taylor). In some cases, however, that are mortal, the symptoms of shock are but slight.

The **Primary Hæmorrhage** from gun-shot wounds varies according to the situation of the injury and the size of the vessels injured; *cæteris paribus*, these wounds bleed less than other injuries. When the fleshy parts of a limb are perforated by a bullet, the hæmorrhage is often very trifling, the vessels divided being small, and contused rather than cut across. But, though it may be stated as a general rule that gun-shot wounds do not bleed much, yet when a large artery, as the carotid, iliac, or femoral, is torn across, violent and rapidly fatal hæmorrhage will occur—the vessel bleeding as freely as if divided with the knife. Bullet-wounds of the large and deep arteries of the chest and abdomen are almost immediately fatal from hæmorrhage. The greater number of those who die on the field of battle perish from this cause. It has often been observed that arteries escape, though lying apparently in the direct track of a ball. In such cases, however, though primary hæmorrhage do not occur, the liability to secondary hæmorrhage is great, in consequence of the artery, which has been contused by the passage of the bullet, sloughing at a later period. The liability to primary hæmorrhage would appear to be much greater in wounds produced by bullets of very high velocity which cut through the vessels, rather than merely contuse them. This was indeed the experience of the Chilian War of 1892, in which the Mannlicher rifle was used. If the whole of a limb be torn away by a cannon-shot, the arteries of the jagged stump do not bleed, for the same reasons that those of a limb torn away by machinery do not; viz., the contraction and retraction of the ruptured internal and middle coats, and the twisting of the fibrous external coat over them.

Gun-shot wounds, under ordinary circumstances **Inflame**, with much **Swelling, Infiltration, and Tension**. That this should be the case is not surprising when we consider the nature of the wound and the mode of its infliction. The tissues through which the bullet passes are violently contused, the parts actually touched by the projectile are killed, and those a little more

remote are bruised and damaged to such an extent that if exposed to any further irritation, as tension or the presence of putrid matter, they readily perish. The bones, if they lie in the track of the bullet, are splintered and fissured, and the fragments are displaced and driven into the surrounding soft parts. At the same time the blood finds but an imperfect exit from the wound, and the intermuscular planes of a limb and any cavity that may be opened become distended. The exudation from the injured soft parts, that necessarily follows immediately on the injury, still further distends the part with putrescible fluid. As the nature of the external wound usually renders it almost impossible for it to heal by first intention, the whole of this decomposable matter is freely in communication with the external air, and organisms contained in the atmospheric dust find admission from without. This is often rendered even more certain by pieces of clothing and other foreign bodies being lodged deeply in the track of the bullet. By the third day, therefore, we have developed in a gun-shot wound, unless special means are taken to prevent it, one of the most dangerous conditions to which a patient can be exposed—a large accumulation of putrid matter, deeply situated, with a totally insufficient exit for the discharges. If a bone be broken, or a joint or one of the natural cavities of the body be opened, the condition is so much the worse. The bullet damages only the parts it touches; the extension of the inflammation beyond these parts is entirely due to pent-up and putrid discharges. The extent of tissue actually killed by the contact of the ball is comparatively limited; the wide-spread sloughing that may follow a gun-shot wound is due to the irritation of tension and of the chemical products of putrefactive and pyogenic organisms.

The ordinary course of a gun-shot wound is as follows:—As soon as the patient has rallied from the shock the temperature begins to rise. By the second day the inflammation, consequent upon the irritation of putrid matter and the tension caused by the abundant exudation from the injured tissues, begin to manifest themselves. The pain which, at the moment of infliction may have been but slight, becomes extremely acute, owing principally to the great tension. By the third day suppuration sets in, often most profuse and extensive, not only in the track of the ball, but widely diffused through the neighbouring parts. The discharges are offensive from putrefaction, and find a very imperfect exit by the comparatively narrow openings of the wound. Consequently the patient suffers severely from the absorption of septic matter, the fever being very high and the constitutional disturbance very great; in fact, many die about this time from septic poisoning. Should a more ready exit be established for the discharges, the fever subsides by about the tenth day, as granulations spring up and limit the absorption of the products of putrefaction. A period of great danger in gun-shot wounds is that during which the sloughs separate, usually from the sixth to the twentieth day. At this period **Secondary Hemorrhage** is very apt to come on after slight exertion. Bandenk states that this occurrence is most likely to happen on the sixth day. This may be suddenly fatal, and is always more dangerous than the primary hemorrhage, not only on account of the difficulty of arresting it, but because the patient has already been weakened by septic inflammation, suppuration, and fever. Secondary hemorrhage may occur from causes other than the separation of the sloughs and the consequent opening up of a constricted or inflamed artery. It may take place from an artery wounded by a speculum

of fractured bone ; and from the same cause it may arise at any period until all detached bone is separated and the wound firmly cicatrized. Chisholm, of the American Confederate army, mentions a case of death from secondary hæmorrhage on the 328th day after a gun-shot fracture of the upper third of the thigh, owing to a wound of the femoral artery by a detached sequestrum. Independently of this danger from secondary hæmorrhage, the patient, if his limb be saved, may have to undergo long and tedious processes of exfoliation of dead bone, and to run the risk of intercurrent attacks of erysipelas, hospital gangrene, and pyæmia.

Although a bullet wound in the vast majority of cases follows the course above described, inflammation and profuse suppuration are not inevitable results. Middleton Michel, of Charlestown, U.S.A., relates many cases of gun-shot wounds, inflicted by the Minié rifle bullet, which healed without suppuration even when the bones were injured ; and union by first intention has occurred in wounds made by the Lee-Metford bullet. Such cases are sufficient evidence that the destruction of tissue caused directly by the action of the bullet is not so extensive as was at one time supposed, and that, could perfect drainage be combined with prevention of decomposition, gun-shot wounds would be robbed of half their dangers.

There is every reason to believe that warfare in modern times is fully as destructive to life as it was formerly, if not much more so ; not in the proportion of the killed to the number of combatants engaged, but in relation to the recoveries among the wounded. This at first sight appears remarkable, when we consider the great advances that have been made in surgical treatment and in sanitary arrangements. But unfortunately the means by which these great advances have been brought about are seldom at the command of the military surgeon. A very large proportion of gun-shot wounds must occur under circumstances which render antiseptic treatment uncertain or impossible ; whilst the enormous number of men engaged has yielded so large a number of sick and wounded that, after the first few weeks, the sanitary arrangements have hitherto broken down under the pressure, and secondary septic diseases have made the most frightful ravages. Moreover, the advance in surgical treatment has up to the present time been more than neutralized by the more deadly nature of the injuries.

TREATMENT.—The slighter and superficial gun-shot injuries generally require merely to be treated on the ordinary principles that guide us in the management of contusions and lacerations generally. When they affect the head, chest, or abdomen, they present so many circumstances of special importance, that we must defer the consideration of them until we treat of injuries of those regions.

In all cases of gun-shot wounds, certain *immediate attentions* are necessary in order to place the sufferer in some degree of comfort and safety until more definite treatment can be adopted. It is impossible on the field to carry out antiseptic treatment with the same certainty as in a general hospital, but a great deal can be done to avoid unnecessary contamination of the wound. The fate of the soldier is truly, as Nussbaum has said, in the hands of the Surgeon who first attends him. If primary antiseptic treatment is at once used, he will have an infinitely better chance than by any other method.

It is generally believed that unless a portion of clothing or some other foreign body is carried in by the bullet, the wound may be regarded as aseptic

immediately after its infliction, infection occurring most commonly as a consequence of the introduction of an unpurified finger or probe. It is therefore now laid down as a rule that no examination of the wound should be made and no operation undertaken, except for the arrest of hæmorrhage or immediate preservation of life, until the patient has been removed to a field-hospital in the rear, where antiseptic treatment can be efficiently carried out. On the field the treatment should as far as possible be limited to the application of a pad of some absorbent antiseptic material, secured by a triangular handkerchief or a bandage. This first dressing is in most armies carried by the soldier as part of his kit.

In the British army the field dressing is sewn into a pocket on the inside of the skirt of the jacket. It consists of a compress of charpie between layers of gauze, a separate piece of gauze, and a gauze bandage. These are rendered antiseptic with 1 in 1,000 solution of corrosive sublimate. The dressing is wrapped in thin mackintosh and sewn in an outer cloth covering. A tablet of perchloride of mercury and salt (p. 208) might be added, sufficient to make a pint of 1 in 500 lotion, with which the skin might be washed before applying the pad, provided water could be obtained. Under treatment similar to this gun-shot wounds have not unfrequently healed by scabbing, even when implicating bone or joints, although so fortunate a result cannot be relied upon. Iodoform can hardly be carried in any form as a "first dressing" owing to its unpleasant smell, but enough to dust the apertures of entry and exit of many wounds could easily be carried by the Surgeon on the field, and by this means asepticity might possibly be rendered more certain. All ideas of syringing out the wound with an antiseptic and the insertion of drainage-tubes on the field are now abandoned as impracticable. If a bone or joint be injured, the limb must be placed on a splint of some kind, extemporized from such material as may be at hand. A bayonet forms a useful splint for the leg, arm, or forearm; and for the thigh a rifle may be applied to the outer side of the limb with the stock against the side of the body.

If there be abundant venous hæmorrhage, the limb should be raised; and if this do not arrest the bleeding, a compress should be used. If the hæmorrhage be arterial, a tourniquet must be applied. So, also, a tourniquet should be employed if there be rapid dripping of blood.

If a limb be smashed, or torn away, a tourniquet should be applied to the stump, which must be covered up with wet cloths. The pressure of the tourniquet will not only arrest hæmorrhage, but will stay that spasmodic quivering of the muscles which is so painful to the sufferer.

If the head or neck be wounded, the wound must be treated as above described, and hæmorrhage, whether venous or arterial, should be arrested by pressure with the fingers.

If the chest be shot through, the patient should be laid on the injured side, and cold employed. If emphysema occur, or if air pass freely through the wound, a body-bandage must be tightly applied.

If the abdomen be wounded, the patient should be laid on the injured side, if the aperture be lateral; if it be central, on his back, with the knees bent over a log or knapsack, or other support. If the intestine protrude, it must be washed and returned at once.

In addition to these immediate attentions which may be bestowed upon sufferers from gun-shot wounds before they are sent to the hospital for more

methodical treatment, the influence of the shock and pain should be counteracted by the administration of a little brandy-and-water and opium, and plenty of cold water should be given to relieve thirst.

Gun-shot Wounds in the Extremities may be divided into two great classes in reference to treatment :—I. Those that do not require amputation : II. Those in which amputation is necessary.

I. Those cases of gun-shot injury which **do not require amputation** must be treated on the principles that guide us in the management of other wounds ; the Surgeon bearing in mind, however, that these injuries, unless they can be kept aseptic, are especially apt to be followed by severe diffuse inflammation, and that sloughing is very prone to occur in the track of the ball.

The first point to be attended to in these cases is the **Arrest of Hæmorrhage**. In general, this may not give

much trouble : but, if a large vessel be injured, the loss of blood will rapidly prove fatal. The bleeding may in the first instance be stopped by direct pressure with the fingers on the bleeding part, followed by the application of the tourniquet, the most convenient form being the simple elastic band. If this be not at hand, some substitute must be made use of, such as a pebble, of about the size of an egg, placed in the middle of a pocket-handkerchief and laid over the artery, the handkerchief being knotted round the limb, and then twisted up tightly with a piece of stick or the hilt of a sword passed under it (Fig. 109). The wound in the artery may render amputation of the limb necessary ; if not, hæmorrhage must be arrested by making an incision down to the bleeding vessel, and applying a ligature on each side of the wounded point, for reasons that will be stated when we come to speak of Injuries of Arteries. In military practice,

Fig. 109—Gun-shot Wound of Thigh : Mode of Compressing Artery temporarily.

however, such operations for primary hæmorrhage appear to be very rare. The fact is that, if a large artery be wounded, the patient usually dies from hæmorrhage before anything can be done to arrest it. If a small vessel only be divided, the hæmorrhage will speedily cease of itself.

The second point to be attended to is the **Extraction of Foreign Bodies**, such as shot, slugs, or bullets, wadding, pieces of clothing that have been carried in with the ball, splinters of bone, and other matters of a like kind. This, for the reasons already given, should not be undertaken on the field of battle, nor is it necessary to examine the wound as soon as the patient arrives at the hospital in all cases if it is known that the bullet has not lodged. If an antiseptic first dressing has been applied and is drying on the wound, it may be left in the hope of scabbing taking place, unless a rise of temperature and increased pain show that suppuration is commencing. The modern rifle bullet, owing to its conical form and its great velocity, does not in the

majority of cases carry any portion of the clothing with it. If foreign bodies are carried into the wound they will generally be found near the aperture of exit, through which they may often be more easily extracted.

If the *bullet* lodge, it, together with any foreign bodies accompanying it, must be extracted through the wound, or cut out by a counter-opening. This second opening is often of great utility in affording a ready exit for subsequent discharges. Palpation of the limb or region struck will often lead to the discovery of the bullet, when it lies among the muscles or beneath the skin. A consideration of the direction whence the bullet came, and the position of the patient when hit, will often direct attention to the spot where the ball has lodged. If possible, the same position of body or limb should be assumed; the track of the bullet will thus be straightened, and the finger or probe can be carried down to it more readily. In searching for bullets and other foreign bodies, care should be taken not to probe the wound unnecessarily from mere curiosity, or so as to excite irritation; in many cases, the introduction of the finger is far more useful than that of the probe. The advice given by Ambroise Paré, three hundred years ago, with regard to the examination of gun-shot wounds, can scarcely be improved upon. After recommending that the examination of the wound be made as soon after the injury as possible, before swelling and inflammation set in, he says: "This is the principal thing in the performance of this work, that you place the patient in just such a posture as he was in at the receiving of the wound: for otherwise the various motions and turnings of the muscles will either hinder or straiten the passage forth of the contained bodies. You shall, if it be possible, search for these bodies with your finger, that you may the more certainly and exactly perceive them. Yet, if the bullet be entered somewhat deep in, then you shall search for it with a round and blunt probe, lest you put the patient to pain." The *extraction of the bullet* should be accomplished without delay, before inflammation has set in, and the lips and sides of the wound have become swollen. As Macleod justly observes, the extraction of the ball removes a source not only of physical irritation and suffering, but also of mental disquietude. Bullets cannot, as a rule, be allowed to remain lodged in the body with impunity. It is true that in some cases they become encysted, and so cease to irritate; but in the great majority of instances they produce suffering and constitutional disturbance, and may at last occasion fatal mischief: for, although a bullet may continue fixed for years, yet it may at last, under the influence of muscular action, gravity, or the absorption of fat, begin to move and give rise to injurious consequences. The bullet should, therefore, always be removed when possible, but if it is not readily found the attempt to discover it should not be continued too long, as more harm may result from this than from leaving it. If any foreign body be very tightly fixed, so that it cannot easily be removed, it must be left till loosened by suppuration. Sometimes a bullet is firmly fixed in the cancellous structure of the articular end of a bone, and must be removed by means of an elevator.

Various instruments are used for the detection and removal of bullets and other foreign bodies. There is usually no material difficulty in detecting the presence of a bullet, by means of an ordinary steel probe of sufficient length. When, however, the bullet is lodged deeply in the cancellous structure of a bone, or amongst swollen and infiltrated tissues, the difficulty may be great. Nelaton, in the case of Garibaldi, adopted the ingenious device of passing a

probe armed with a piece of unglazed porcelain down to the suspected site of the bullet, and noting the streak of lead left on the rough surface. Bullet-detectors have also been contrived, in which, by an arrangement of two insulated metal probes in a cannula connected with a galvanometer, the galvanic circuit is completed when the bullet is touched, and the needle of the galvanometer deflected: or, instead of the latter instrument, the ordinary telegraph alarm may be interposed, the bell of which rings when the circuit is completed by the bullet or any other metallic body being touched. These various contrivances are more ingenious than practical, and may be looked upon as surgical toys rather than as useful instruments. For the removal of bullets, long and strong forceps are required, the action of which may be aided by a screw probe.

The *splinters* produced by the passage of a ball through a bone are more numerous and larger when the injury has been inflicted by a conical rifle-ball. The impetus of this projectile is so great, and its wedge-like action so destructive, that the bone struck is shattered into a number of fragments, as well as split longitudinally, often to a great extent. These fragments are detached to a greater or less extent from their connections with the soft parts, and carried out of the axis of the limb. Dupuytren, who was fond of systematizing, classified splinters of this kind under the three heads of *primary*, *secondary*, and *tertiary*. *Primary* splinters are carried completely across the limb, detached from the soft parts, and lodged near the aperture of exit. *Secondary* splinters remain still attached by a strip of periosteum or fibrous tissue: *tertiary* are those portions of bone which, from the violence done to them, often necrose and separate at a subsequent period. The treatment of these different kinds of splinters must necessarily vary. The primary, which are already completely detached and are incapable of consolidation, must be treated as foreign bodies and extracted. The secondary, if very loose, must also be removed: but, if more firmly fixed, they may be pushed into the axis of the injured bone and left, when they may become consolidated by callus, and so serve in the reconstruction of the bone. The tertiary, which do not separate until after about six or seven weeks, must be removed as soon as possible; if they become engaged in a mass of callus, it may be a considerable time before they are loose enough to be removed; and, until then, sinuses leading down to them will remain open even for years.

The reunion of comminuted gun-shot fractures may, in appropriate cases, be assisted by resection of the fractured ends of the bones. This plan has been especially successful in the bones of the upper extremities. After resection of the ends the fragments may be kept in apposition by metallic sutures, as suggested by Howard, of the American army.

In those cases in which small shot are lodged under the skin, they may be removed by being cut down to with a fine scalpel; when more deeply seated, no attempt should be made to extract them.

The **Treatment of the Wound** itself must be conducted on ordinary surgical principles. As has already been stated, there will, as a rule, be violent inflammation and sloughing along the whole track of the ball, unless decomposition can be prevented; although instances have been recorded of primary union in gun-shot wounds, uncomplicated with fracture or the lodgment of foreign bodies, even without any special mode of antiseptic treatment. The principal points to be attended to are: to limit inflammation by rest, drainage,

and the use of antiseptics, to watch and facilitate the separation of sloughs should they form, and to pay scrupulous attention to cleanliness and the general hygienic surroundings of the patient.

By adopting some form of *antiseptic treatment*, inflammation may be limited, and the formation of sloughs avoided; in both civil and military practice the repair of gun-shot fractures without suppuration has been frequently obtained by this mode of dressing.

In cases occurring in civil practice the employment of antiseptics with all needful precautions is easy, and the results are correspondingly satisfactory. Kraske has published a series of twenty-three cases under the care of Volkmann in Halle, treated by strict antiseptic dressing with enlargement of the apertures, both of entry and exit, to facilitate drainage. Of these two died—one a perforating wound of the skull, and one wound of the abdomen perforating the liver, kidney, and pleura. The twenty-one cases that recovered were the following: five flesh wounds, two flesh wounds requiring primary ligature of the femoral artery for hæmorrhage, two of the arm with fracture, four wounds of the knee-joint, two perforating wounds of the skull, and six of the chest.

In military practice it is to be hoped that the simpler modes of dressing now adopted will make it possible to carry out efficient antiseptic treatment even after such battles as those of the Franco-German war. At the time of the Russo-Turkish war of 1876-77 the generally accepted antiseptic treatment was that by means of carbolic acid, including the use of the spray and the gauze dressing, and several of the Russian Surgeons attempted this. Bergmann, however, according to Surgeon-Major Melhadew, found it impossible to carry it out with anything like completeness at the crossing of the Danube, where the wounded were comparatively few. The river-water was full of sand and mud, which soon choked the spray-producers, and rendered them useless; and no amount of carbolic acid was sufficient to purify it so as to take away its foul smell. Then, again, the skin of the wounded soldier, begrimed with the dust and sweat of long marches, could not be cleansed with the appliances usually at hand.

But yet, notwithstanding all these drawbacks, the antiseptic treatment did more than had ever been effected by any other; for it was by means of it that Bergmann and Reyher saved almost all their cases of gun-shot wound of the knee-joint. Reyher, who had provided himself with all the materials for Lister's carbolic gauze treatment, adopted two modes of dressing. If the apertures of the wound were very small, and no foreign bodies or splinters of bone required removal, he simply washed the skin externally with 1 in 20 solution of carbolic acid, and applied a dry gauze dressing, which was left untouched, the wound being allowed if possible to heal by scabbing beneath it. If the apertures were large, and splinters of bone had to be removed, he carried out Lister's treatment in all its details, with injection of the wound, drainage, and repeated dressings. By both these modes of treatment he obtained a large measure of success.

The best mode of carrying out the antiseptic treatment is still undetermined, but perchloride of mercury seems the most practically useful agent for cleaning the skin, disinfecting the wounds and impregnating the dressing. Carbolic acid would only be required for the instruments used during operations. The advantages of the perchloride are that it can be carried in

the solid form and occupies little space ; it is one of the most powerful of all antiseptics, and the Surgeon himself or his assistants can by means of it easily convert any absorbent substance into an efficient antiseptic dressing, which, when applied, may be left undisturbed as a lasting dressing in a large proportion of cases.

The use of iodoform is strongly advocated by some Surgeons, but it is doubtful whether it would prove as efficient as the perchloride of mercury in the prevention of the effects of the unavoidable overcrowding which follows a battle.

In order to limit the inflammation, it was in former times a common practice with military Surgeons, and still is so with the French, to enlarge by incision the wound made by the ball, with the view of providing a better exit for discharges and preventing tension. John Hunter, who regarded the inflammation and sloughing that occur in gun-shot wounds as dependent solely on the contused nature of the wound, maintained that this practice only superadded another injury to the one already inflicted by the bullet ; and following his precepts, British Surgeons have employed the knife in the early stages of gun-shot wounds only for the purpose of facilitating the ligature of bleeding vessels, or the extraction of foreign bodies. In the more advanced stages, however, free incisions, which should be made in the direction of the axis of the limb, are commonly required in order to lessen inflammatory tension, to prevent the extension of sloughing, and to favour the escape of discharge.

At the present time, however, when the necessity of perfect drainage is so fully understood, it becomes a question whether it would not be better practice to enlarge the wound when it is evidently too small to give a perfectly free exit to the discharges. Such a line of practice undoubtedly facilitates the antiseptic treatment, when union by scabbing is not obtained, as it renders the cleaning of the wound more easy, and for this reason it was adopted by Volkmann in the cases before alluded to.

If the Surgeon is unable to adopt any antiseptic dressing, the best mode of lessening inflammation in a gun-shot wound in the early stages, and more especially in hot climates, is cold irrigation, or if possible the application of dry cold by means of ice in india-rubber bags, conjoined with drainage and rest. As suppuration comes on, warm applications must be substituted for the cold, so as to hasten the formation of matter and the separation of the sloughs, whilst disinfectants should be freely used to the whole cavity of the wound. All bagging and burrowing of matter must be carefully guarded against by position, pressure, drainage, and counter-openings. Free incisions may also now be required. These should not be delayed too long. They may be required for three purposes : first, to relieve the tension resulting from infiltration of the limb by inflammatory effusions ; secondly, to open up purulent collections and give exit to the decomposing discharges, and thus to remove the constitutional disturbance dependent upon the absorption of the elemental productions of putrefaction ; and thirdly, to extract splinters of bone, portions of clothing, and other foreign bodies that could not be removed in the first instance. When the inflammation is very acute and will not yield to the measures just enumerated, it has been recommended to compress or tie the main artery leading to the part ; there can be no harm in trying the former, but the latter is not justifiable. At the period of the sloughing and separation of the sloughs, there is always especial danger of the

supervention of consecutive hæmorrhage. The patient, consequently, at this time requires to be carefully watched : if the wound be in the vicinity of a large vessel, a tourniquet should be placed loosely round the limb, so as to be screwed up at a moment's notice ; and, on the occurrence of bleeding, the artery must be ligatured, if possible, at the seat of the wound, or, if this be not practicable, in the most convenient situation above it. If this do not arrest the bleeding, recourse should be had to amputation.

Serious results, such as abscesses, profuse discharges, osteomyelitis, necrosis, and the separation of splinters of bone, must be subsequently looked for in many cases ; and these results may be prolonged for many years, at last perhaps wearing out the patient if the cause of irritation be not removed. Thus General Bem required to have a bullet removed by Liston from the external condyle of his femur, nineteen years after it lodged there ; and Marshal Moncey died from the effects of a gun-shot wound, forty years after its receipt. A soldier who was wounded at the storming of the Redan died under my care in the University College Hospital, two years and a half after that event, of exhaustion resulting from a large lumbar abscess. On examination it was found that the bullet, which had entered the left side of the chest, wounded the lung, traversed the diaphragm, notched the spleen, passed between the kidney and suprarenal body, and perforated the spine, was lying encapsuled on the right side of one of the vertebrae, pressing upon the right renal vessels. Its irritation, and that of the sequestra from the injured spine, produced the abscess, from the effect of which the patient died.

The aperture of exit usually heals sooner than the aperture of entry, probably owing to the more extensive sloughing that often takes place round the latter.

II. Amputation is required in gun-shot injuries in two classes of cases very dissimilar in character.

First, in cases in which the limb is wholly or in part carried away or so shattered that there could be no doubt in the mind of any Surgeon as to the necessity for immediate amputation ; and secondly, in various cases in which a Surgeon, judging solely from the accidents of civil life, might not at first think the operation necessary. For example, in a bullet wound of the knee-joint, the apparent injury may be very slight, yet experience has shown that an attempt to save the limb under circumstances in which efficient antiseptic treatment cannot be adopted, rarely, if ever, succeeds.

The following is a specification of the chief conditions in which amputation is required. We have still to learn how far the use of antiseptics will enable us to modify some of these rules ; but it is probable that the military Surgeon of the future will not always have the necessary materials at his command for strict antiseptic treatment, and he must then be guided in his practice by his experience of former times, and resort to amputation in cases in which, under more favourable conditions, there might be a fair prospect of saving the limb.

1. When the whole limb is carried off, a ragged stump merely being left ; so, likewise, if the limb be completely crushed and disorganised though still left attached ; or again, if the principal vessels be injured and the soft parts carried away, though the bone be intact, the limb cannot be preserved.

2. Amputation is especially necessary in some of the more serious injuries of the lower extremity. Thus, if a bullet divide the femoral vessels or the sciatic nerve, and splinter the thigh-bone ; or if the sciatic nerve and soft parts

at the back of the thigh be carried away, although the vessels and bone be left uninjured, the case is one for amputation. It may be stated generally (though, doubtless, there are exceptions to this, as to all general rules in surgery) that in the case of a *compound fracture of the lower third of the femur* occasioned by gun-shot, amputation is the safer practice, unless the patient is likely to be placed in exceptionally favourable circumstances after the wound and the Surgeon has at his command all the means necessary for efficient antiseptic treatment.

The mortality, however, after amputation for gun-shot injury of the *upper two-thirds of the thigh*, is so great that many Surgeons have abandoned the operation in these cases, and professional opinion is unsettled as to the course that should be pursued. In the Schleswig-Holstein war of 1849, it became a question with many of the German and Danish Surgeons whether this operation should be continued, or whether the patient would not have a better chance if the injury was treated on ordinary principles as a compound fracture. At the siege of Sebastopol, the mortality after amputation in the upper third of the thigh was so great in the Russian Army that the Surgeons abandoned the operation. On the other hand, it is stated in the Report of Black Sea Fleet, that to attempt to save the limb in any case of gun-shot fracture of the thigh was to endanger the patient's life. In the Crimea, according to Macleod, a bad compound fracture of the thigh from gun-shot was synonymous with death. This was partly owing to the bad health of the troops, and partly to the terrible effects of conical balls.

Macleod states that, although he made every inquiry, he could hear of only three cases in which recovery had, in the Crimea, followed a compound fracture of the upper third of the thigh-bone without amputation. But, exceptional as were such recoveries, he states that they were not so rare as after amputation for similar injuries: as indeed was proved by the fact that not one patient recovered after amputation at the hip-joint. Hutin, the Surgeon to the Invalides in Paris, was able to discover twenty-four cases of recovery after compound fracture above the middle of the thigh, but no case of recovery after amputation for injury of the same part. In the British army in the Crimea, the amputations in the upper third of the thigh, which must have been for compound fractures low down in the bone, were fatal in the ratio of 86 per cent.: of those in the middle, probably for injuries of the lower articular end and knee, 60 per cent. died; whilst of those in the lower third, which must have been for injuries of the knee and leg, the mortality was reduced to 56 per cent. The conclusions at which Macleod arrives, after a careful inquiry into this question, are so important, that I give them in his own words. He says: "Under circumstances of war similar to those which occurred in the East, we ought to try to save compound comminuted fractures of the thigh when situated in the upper third; but immediate amputation should be had recourse to in the case of a like accident occurring in the middle and lower thirds." In the civil war in America, the opinions of Surgeons appear to have been divided; and the conclusion arrived at seems to have been that, provided the large vessels and nerves were not injured, and the circumstances in which the patient was placed as to conveyance not too unfavourable, the chance of recovery would be equal whether amputation were performed or an attempt made to save the limb. But even in these circumstances Hamilton states that, although his experience in that great war has led him to the conclusion

that in the upper third life is least hazarded by an attempt to save the limb, in the middle third conservatism and amputation afford an equal chance, whilst in the lower third of the thigh the chances are in favour of amputation. This is a conclusion very similar to that arrived at by the British Surgeons.

When an attempt is made to save the limb, the skin should be cleaned on the field of battle, if possible, with some strong antiseptic, and the limb enveloped in a large mass of some absorbent antiseptic dressing, over which a plaster-of-Paris bandage should be applied as soon as the patient reaches the field hospital. This dressing may be left untouched, unless some special circumstances require its removal, for some days until the patient reaches the hospital in which the further treatment is to be carried out. In some rare cases healing will take place under a dry scab. If at the end of four days the patient is suffering no pain and is free from fever this fortunate result may be looked for; in other cases the primary dressing should be removed about that time, and during its further progress the case must be treated by extension and counter-extension, and the free use of antiseptics, and the limb may be securely fixed in a plaster-of-Paris apparatus with a window opposite the wound.

3. In gun-shot fractures of the *bones of the leg*, amputation becomes necessary if the tibial arteries be injured, or if the knee or ankle-joint be badly wounded. If the injury be in the middle of the leg, at a distance from these joints, and provided there be not longitudinal fissuring of the bone leading into them, much may be done to save the limb, by the extraction of splinters and the removal of sharp and angular fragments of bone, the limb being put up in the plaster-of-Paris apparatus. In such cases, the patient may recover with a shortened, but otherwise useful, limb.

4. Gun-shot wounds of the *foot*, if perforating and splintering the tarsus, may commonly be saved by antiseptic treatment, but if this be not possible they require amputation, either at or above the ankle. Those of the *hand* are of special interest from their frequency, in consequence of the bursting of guns, or of powder-flask explosions. In these cases, however extensive the injury may be that is inflicted upon the hand—fingers being blown away, the thumb thrown back, and the metacarpal bones splintered—we must endeavour, if possible, to save a portion of it, if it be only one or two fingers; and, owing to the great reparative power possessed by the hand, we shall often, in the worst-looking cases, be able to accomplish this. If the thumb, with one finger as an opponent, can be preserved, it will be of more service to the patient than any artificial contrivance, however ingeniously made.

5. It may happen that amputation becomes necessary in the later stages of gun-shot injury, in consequence of mortification. In these circumstances it must be practised without delay, and without waiting for the line of separation. If, in consequence of long-continued suffering and discharge, the patient's health become greatly deteriorated, and the limb remain a useless appendage, amputation will at last be imperative.

6. Gun-shot injuries of *joints* are necessarily most serious and fatal, the danger depending on the size and complexity of the articulation, rather than on the extent of the injury. Wounds of any of the three large joints of the lower extremity are especially dangerous: those of the upper extremity are more commonly recovered from. The fact of a joint being wounded is gene-

rally obvious enough from the direction taken by the ball, the comminution of the bones, and perhaps the escape of synovia; but a joint may be fatally injured by the longitudinal splitting of the bone into it, although the bullet has not passed within some inches of it.

In bullet-wounds of joints, excision may be advantageously substituted for amputation in cases in which the soft parts are not too extensively torn, the large nerves and vessels are uninjured, and the shaft of the bone is not too widely splintered, the mischief being confined chiefly to the articular ends.

Bullet-wounds of the *head, neck, or trochanters of the femur, splintering the bone into the articulation*, are necessarily most serious. If they be left to palliative treatment, the death of the patient may be considered as almost inevitable; if amputation at the hip be performed, the prospect is better, and, though desperate, the case must not be considered hopeless. This is well illustrated by the result of amputations in the American Civil War. In *Primary* amputations at the hip-joint for gunshot injury, the mortality was, according to one estimate, 94, according to another, which I think more correct, 84 per cent. All *Intermediate* amputations were fatal; the *Secondary* ones only at the rate of 77 per cent. If the shaft be not too much implicated, it is probable that the best hope lies in excision of the splintered head of the bone, and careful removal of the loose fragments. This operation, originally proposed by Guthrie, and first successfully performed by O'Leary in the Crimean war, presents the most reasonable, though but a slender, hope of safety to the patient, and should accordingly be practised. With this view the wound must be laid freely open, loose fragments extracted, and the upper end of the bone detached, turned out, and sawn off. Of six cases in which this was done in the Crimea, one patient, O'Leary's, recovered. Gurli, who has collected all the cases of excision of joints for gun-shot wounds which have been recorded since 1792, states that excision of the hip has been performed 139 times; 16 of the patients recovered, 122 died, and the result of the remaining case is uncertain.

Bullet-wounds of the *knee-joint* are among the most serious injuries in surgery; and this whether the bones be much comminuted or not, provided the epiphysis of the tibia or femur be perforated, or the articulation be fairly traversed or even penetrated by the ball. Prior to the American war there were seven cases in which excision of the knee had been done for gun-shot injury—five in military, two in civil practice; the two latter cases recovered, the other five died. In the American war the operation was done eleven times: in two cases, one primary, the other secondary, recovery took place; one death resulted, chiefly from pyæmia. In three cases in which the patella alone was excised, death ensued. Gurli has collected the records of 146 cases, of which 33 recovered, 111 died, and the result was uncertain in the remaining cases. These results are so bad that the operation for the future will probably be abandoned in military surgery. It is in this class of cases, however, that Bergmann and Reyher have obtained a very considerable measure of success by conservative treatment, with strict antiseptic dressing. Bergmann had 15 fresh gun-shot wounds of the knee under his care after one of the battles in the Russo-Turkish war. These were all treated by superficial cleaning of the skin with carbolic lotion and the application of a mass of sterile wool, especially thick at the knee, secured by an elastic bandage and covered with a plaster-of-Paris apparatus. They were then immediately sent

on a four days' journey, under great difficulties from roads and weather, to the hospital at the base of operations. Of these 8 recovered without suppuration, 2 suppurated slightly, and 5 severely. Of these 5, 2 recovered without amputation, 2 after amputation, and 1 died of pyæmia. Reyher, by the employment of Lister's gauze, either as a permanent dressing to obtain healing by scabbing, or with drainage, obtained the following results : In 18 cases which came under his care before they had been probed or examined the wound united under the dry dressing, without suppuration, in 10 ; in 4 he treated the wound by antiseptic drainage and of these 3 died ; and in 2 drainage was commenced at a later period of the case and both recovered. Thus of the 18 cases treated primarily by antiseptic dressing, 3 died, and all the survivors preserved the limb with a considerable degree of mobility in the joint. Forty cases which had been "fingered" before he saw them also came under his observation. Of these 19 were treated by drainage after occlusion had failed and 18 died ; in 9 others intermediate amputation was performed, with 7 deaths ; in 12 secondary amputation was performed, with 9 deaths ; making a total of forty cases, with 31 deaths, and only one limb saved. Conservative treatment was attempted without antiseptic dressing in 23 cases, and of these only one finally recovered, and in that healing took place by scabbing under a dry dressing.

In all cases in which antiseptic treatment is impossible, conservative treatment contrasts most unfavourably with primary amputation in the lower third of the thigh. When amputation is determined on, the operation requires to be performed early, not because the apparent injury may be very severe, or the mutilation of the limb so great as obviously and imperatively to call for immediate amputation, but because experience has shown that, unless the limb be removed at an early period, after-consequences of the most serious and fatal character will to a certainty ensue. Extensive suppuration of the joint, deep and large abscesses burrowing among the muscles of the thigh, and consequent exhaustion of the patient by hectic, or his destruction by pyæmia, are the conditions that amputation alone, performed at an early stage, can avert. This necessity for early amputation in penetrating bullet-wounds of the knee-joint, when antiseptic treatment is impossible, is recognised by all modern military Surgeons. Guthrie and Larrey in the French wars, Esmarch and Stromeyer in the Schleswig-Holstein campaign, and the Surgeons in the Crimea, all found that the attempt to save a limb so injured led to the sacrifice of the patient's life.

Bullet-wounds of the *ankle-joint* do not necessarily require amputation. If the bones be not too extensively comminuted, and more particularly if the posterior tibial artery and nerve have escaped injury, an attempt may be made to save the limb, and will probably be successful ; the injury being treated on the principles which will be described in the chapters on Fractures and on Dislocations. In such cases extraction of fragments, and excision of the splintered ends, are necessary ; and modified operations, partial excision by means of gouge, forceps, and Hey's saw, will be found more successful than the more systematic operations. Guilt has collected 150 cases of excision of the ankle, with 94 recoveries, 51 or 34 per cent. deaths, and 5 uncertain. If the large vessels and nerves have been cut across, and the bones very extensively shattered, amputation will be the proper course to pursue.

The *shoulder*, and more particularly the left shoulder, from its advanced

position in the act of firing, is peculiarly liable to gun-shot injury; the bullet either lodging in the head of the humerus or traversing it, and perhaps fracturing some of the bony processes of the scapula in its immediate vicinity; or, as in the case of fragments of shells, carrying away a large part of the deltoid muscle. It is especially in bullet-wounds of the shoulder and elbow-joint that conservative surgery has been most successful. In such cases, when the bones are penetrated, and even shattered by a bullet, provided the main blood-vessels and nerves of the limb be not injured, amputation will seldom be required; and indeed, it should be laid down as a rule in surgery, that excision should be preferred to amputation in all cases in which the large blood-vessels and nerves are not wounded, or the soft parts too extensively disorganised. The wound having been enlarged, loose spicula must be removed, and the splintered and jagged ends of the fractured bone sawn smoothly off. If the bullet be still lodged in the head of the humerus, as in Fig. 110, the same course should be adopted. It has been a question with Surgeons whether excision or amputation should be done when the upper end of the shaft of the humerus has been much splintered, with or without penetration of the joint.

In these cases the head of the bone is often uninjured. Guthrie advised amputation; but the result of the experience of the war in America has been that five or six inches of the shaft of the humerus may be removed with perfect safety, and that no good comes of leaving the uninjured head, which should also be excised. The results of excision of the joints of the upper extremity are in the highest degree satisfactory. Thus Baudens states that he saved 13 out of 14 cases of excision of the shoulder. According to Thornton, in the British army in the Crimea, the shoulder was excised 12 times with 2 deaths; the elbow in 17 cases, of which 2 were fatal; and partially in 5 other cases, all of which were successful. These results were more successful than those that followed amputation of the corresponding parts. Of 60 disarticulations at the shoulder, 19, or 31 per cent., were fatal; and of 153 amputations of the arm, 29, or 19 per cent., died. The result of resection of these joints has not been quite so satisfactory elsewhere; thus, in the Confederate army in America, Chisholm states that up to February, 1864, of 59 cases of excision of the shoulder, 20 proved unsuccessful; and of 66 cases in which the elbow was excised, 9 were unsuccessful. In the official report of the Surgeon-General of the United States army, of 286 cases of excision of the elbow in which the results were known, it is stated that 62 died, and in 16 amputation became necessary. Of 210 primary excisions of the shoulder-joint death occurred in 50; and of 298 secondary excisions 115 were fatal, giving a mean mortality of 32.48, against 39.44 for amputation at the shoulder, and 44.4 for cases treated on the expectant plan.

Gurt has collected 1,661 cases of excision of the shoulder in military surgery with 1,067 recoveries, 567, or 34.7 per cent., deaths, and 27 uncertain; and 1,048 of excision of the elbow, with 1,054 recoveries, 349, or 24.87 per cent., deaths, and 35 doubtful.

The operation of excision of large portions of the shaft of the humerus, as well as of its head, was carried much further by the American military surgeons in the Civil War than had previously been done. Fig. 111, taken

Fig. 110.—Spherical Bullet in Head of Humerus.

from photographs in the possession of the Army Medical Department at Washington, represents six inches of the shaft of the humerus with its head, which had been thus excised; and Fig. 112, the arm that was left. I saw the man, who is an orderly in that unrivalled collection, the Army Medical Museum at Washington, and I can testify to the utility of his arm; the bone so skilfully taken away he himself exhibited.

Excision of the wrist, in whole or in part, for gun-shot injury has not proved very satisfactory, not so much from death as from inutility of the hand that was left. Of 27 done in the American war, only 3 died. In two instances, amputation of the forearm was practised.

Gurtt has collected 133 cases with 112 recoveries, 20, or 15.15 per cent. deaths, and 1 uncertain.

The steps of all the operations are the same, whether the excision of the

Fig. 111.

Fig. 112.—Result of Excision of Head and six inches of Shaft of Humerus shown in Fig. 111. (U. S. Army Med. Dep.)

part be required for gun-shot injury, or for disease; except that in gun-shot injury advantage may often be taken of the wound in the soft parts, by enlarging which longitudinally, the shattered bone may be readily reached.

The question as to the *period at which amputation ought to be performed* after the infliction of gun-shot wounds, is one of great importance, and has given rise to much discussion among Surgeons. The older military Surgeons, Pare, Wiseman, Ledran, Ranby, &c., taking a common-sense view of the question, advocated the removal of the hopelessly injured limb as soon as possible after the receipt of the injury. Wiseman's advice is to "cut off the limb quickly while the soldier is heated and in mettle;" and this advice has not been and cannot be improved upon. After the battle of Fontenoy, in the middle of the last century, professional opinion underwent a change upon this subject; an Faure wrote a thesis, which obtained a prize from the French Academy of Surgery, recommending delay in amputating in certain cases. Hunter, Percy

and other Surgeons of repute, expressed similar views; and Bilguer, the Surgeon-in-chief to the armies of Frederick the Great, went to the absurd length of condemning amputation entirely. These extreme opinions necessarily occasioned a reaction; and the experience gained in the wars of the French Revolution and of the Empire enabled Surgeons to settle this question definitively. It was more particularly through the observations of John Bell, Larrey, Thomson, Guthrie, S. Cooper, and Hennen, that the necessity of having recourse to immediate amputation in all cases of gun-shot injury requiring this operation became fully recognised, and the truth of Wiseman's teaching was re-established.

It is to be hoped that the advance of antiseptic surgery will enable the Surgeon to carry out conservative treatment to a much greater extent than has up to the present time been possible. When antiseptic treatment is impossible the rule of performing primary amputation in all doubtful cases must still be followed. Sir Charles Bell has thus graphically described the results of the attempts to save such cases before the days of antiseptic surgery:—"In twelve hours the inflammation, pain, and tension of the whole limb, the inflamed countenance, the brilliant eye, the sleepless and restless condition, declare the impression the injury is making on the limb and on the constitutional powers. In six days, the limb from the groin to the toe, or from the shoulder to the finger, is swollen to half the size of the body; a violent phlegmonous inflammation pervades the whole; serous effusion has taken place in the whole limb; and abscesses are forming in the great beds of cellular texture throughout the whole extent of the extremity. In three months, if the patient have laboured through the agony, the bones are carious; the abscesses are interminable sinuses; the limb is undermined and everywhere unsound; and the constitutional strength ebbs to the lowest degree."

If we appeal to statistics, we shall find that of 300 secondary amputations reported by Faure, after the battle of Fontenoy, only 30 were successful; whereas Larrey saved three-fourths of his primary amputations in the Napoleonic wars. In the Peninsular war, the loss after secondary amputations of the upper extremity was, compared to that following primary operations of the same kind, as twelve to one; and in the case of the lower extremity, the loss after secondary amputation was three times as great as after primary. During the siege of Sebastopol, among 80,000 wounded Russians there were 2000 amputations. Of the primary amputations of the upper extremity, leg, and foot, about one-half, and of the lower and middle third of the thigh, about one-third, recovered; but of all the secondary amputations more than two-thirds died. In the American Civil War there were recorded 17,208 major amputations of limbs (excluding those at the hip and shoulder). Of these, 11,630 were primary, with a death-rate of 32.1 per cent.; 3,905 were performed between the third and thirtieth days with a death-rate of 44.5 per cent., and 1,646 were performed after the thirtieth day with a death-rate of 33.3 per cent. These figures clearly show that if the limb cannot be saved, primary amputation gives the patient the best chance.

But how soon after the infliction of the injury should it be practised? It was the opinion of some Surgeons that there is often an interval between the infliction of the injury and the supervention of the shock to the system, in which the limb may most advantageously be removed. Should the depression

of "shock" have come on, it then becomes a question whether immediate amputation should be practised, or the removal of the limb delayed until reaction sets in. On this point it is obviously difficult to lay down any very definite rule; but it may, I think, be stated generally as the result of the experience of the best Army Surgeons, that, if the shock be not very intense, the limb may, under an anæsthetic, be safely removed. Should the prostration be excessive, and there be reason to fear the possibility of internal injury, it will be wiser to delay operation. But if an unsuccessful attempt at the preservation of the limb be made, and if occasion for its subsequent removal should arise, the Surgeon must wait until suppuration has set in before he operates, the period of acute inflammation and septic fever being allowed to pass by. The most favourable time is usually about the tenth day. Among the cases that require secondary amputation, are any in which traumatic gangrene may happen to set in; here the limb must always be removed without delay. If profuse hæmorrhage from the wound occur, and do not admit of arrest by the ordinary means, secondary amputation may become necessary. So, also, when the bones do not unite, the patient being worn out by profuse discharge kept up by the presence of necrosed or carious bone, or left with a wasted, shattered, and useless limb, its removal is the only means of saving life. The high death-rate after secondary amputation in military practice is, in great measure, due to the unfavourable hygienic conditions to which the wounded soldier is usually exposed from overcrowding and want of necessary appliances. He is thus rendered peculiarly liable to be attacked by pyæmia, septicæmia, and hospital gangrene.

The nature and treatment of gun-shot injuries of special regions, as of the head, chest, and abdomen, will be considered in the Chapters devoted to the description of Injuries of those parts.

CHAPTER XI.

POISONED WOUNDS.

Two classes of poisons may gain access to a wound : first, the non-infective, which have no power of increasing in the living body, and, secondly, those which possess true infective properties and multiply in the tissues or in the blood. In the former class the effect is proportional to the dose, in the latter it is not ; in the former the effect begins to manifest itself immediately, in the latter there is sometimes a period of incubation, during which no symptoms indicate the presence of the poison. Both classes may act locally or generally. When the non-infective poisons produce grave general symptoms, this is due either to the quantity introduced or to the intensity of the virus. The most important of the non-infective poisons are the venom of various insects, the poison of snakes, and the chemical products of putrefaction. Amongst the most important of the true infective poisons are the virus of rabies, of glanders, of malignant pustule, and of certain unhealthy processes in the living human body.

STINGS OF INSECTS.

Stings of Insects. as of bees, wasps, mosquitoes, gnats, &c., though painful, seldom produce any serious results ; yet occasionally they prove fatal, by serving as a starting-point for erysipelas in some unhealthy constitutions, or by giving rise to intense irritation from the multiplicity of the stings, as when bees swarm upon and sting a person ; or they may be dangerous in consequence of the nature of the part that is stung, as the eye, or the interior of the mouth, or the pharynx, as has happened from swallowing a bee in a piece of honeycomb. Mosquito-bites are peculiarly irritating, and when numerous poison the blood, producing nervous depression and great febrile irritation. The venom of a mosquito is very powerful, weight for weight probably more so than that of the most venomous snakes. The bites of some insects, as scorpions, or the tarantula in Italy, give rise to serious and even fatal disturbance. A peculiar train of nervous phenomena is said to follow the bite of the tarantula, hence called "tarantismus ;" a condition that is generally stated to be peculiarly influenced by music, though this has been denied by GAZZIO.

Treatment.—In the treatment of stings of insects the application of cooling lotions or of a cold poultice, or rubbing the part with olive oil, will be found useful. In some cases, more especially in mosquito-bites, or the stings of bees or wasps, touching the part stung with strong liquor ammoniæ or potassæ gives relief, if done at once. In the case of stings from wasps or bees, it should be ascertained that the sting has not been left in the wound. If so, it must be extracted, and the alkali applied.

SNAKE-BITES.

Snake-bites are seldom fatal in England, the viper or adder not possessing a sufficiently energetic poison to destroy a healthy adult, though it might possibly kill a child or a very weak person. Snakes are said to be most actively venomous in warm weather and during the season of procreation. Their bites are most dangerous if inflicted through a vein or near the centre of the circulation, or about the neck and face. In tropical countries the bite of the rattle-snake, the cobra di capello, the puff-adder, or the tobacco-pipe snake is often fatal. The number of persons who are annually killed by snake-bites in those parts of India alone from which returns are procurable amounts to about 12,000, or about 1 in every 5,000 of the inhabitants; and it occasionally happens even in this country that the Surgeon has an opportunity of seeing wounds inflicted by these fearful reptiles in menageries. Thus, Sir E. Home has recorded a fatal case of rattle-snake bite occurring in England. A similar instance has been seen at St. George's Hospital, and another in Paris, both in showmen. The only case of this kind which has come under my own observation occurred some years ago at the University College Hospital. The patient, a keeper at the Zoological Gardens, was bitten on the bridge of the nose by a cobra di capello, the poison-fang having apparently penetrated the angular vein. When brought to the hospital, about half an hour after the accident, he was apparently dying, being unable to speak, swallow, or support himself; the pupils were dilated, the face livid, the heart-action feeble, and he was scarcely conscious. After death, which took place in little more than an hour from the time of the infliction of the wound, the veins of the brain and the cerebral sinuses were found gorged with blood, as were also the lungs and the solid abdominal viscera. The right cavities of the heart were loaded with dark blood, the left being empty; indeed, the phenomena of asphyxia were strikingly marked. In this case, death would appear to have resulted from the poison paralyzing the respiratory centre, at the same time that it exerted some direct injurious action on the blood.

Effects of Snake-poison.—The venom of the cobra has been found to consist of an albuminous fluid of neutral reaction, holding cells in suspension. The researches of Weir-Mitchell, Reichert, Wolfenden, and others have shown that the poisonous properties of the venom of the cobra and other snakes depend upon the proteid bodies which it contains, whilst bacteria and alkaloids are absent. Wolfenden finds that the chief proteids contained in cobra-poison are globulin, acid albumin, and serum albumin. The poison is secreted by a gland communicating by a duct with the hollow fang, and so situated that in the act of biting it is compressed by the muscles of the jaw and the venom is thus forcibly ejected from the fang. When given internally, or applied to the conjunctiva, it does no harm if the mucous surface is unbroken. Snake-poison, when introduced into the system through a bite or puncture, may prove injurious or may kill, either primarily by a direct depressing influence on the nervous system, like that of some narcotic poisons; or, secondarily, by exciting severe diffuse inflammation of the areolar tissue of the part. The intensity of its effects depends upon the quantity injected, and consequently upon the size and vigour of the animal inflicting the wound; one that has been compelled to bite frequently loses its destructive power.

The first mode of death occurs only when the poison is very powerful or the

animal bitten small. Thus the poison of the tobacco-pipe snake is said to be so virulent that it will kill a full-grown man in less than a quarter of an hour. The rattle-snake and the cobra will kill a small animal in a few seconds; and a man, bitten some years ago by a rattle-snake in Paris, died in nine hours; the cobra-bite above mentioned was fatal in little more than one hour; the Australian tiger-snake will kill in less than twenty-four hours.

When the snake is less venomous and death is not speedy, the poison excites diffuse inflammation and supuration of the areolar tissue of the part. This is a very common consequence of the bite of the viper in this country. It may occur also after bites by the larger ophidia. Thus, in the case which occurred in St. George's Hospital, the patient died on the eighteenth day after the bite of the rattle-snake, with large abscesses in the arm and in the axilla, and with sloughing of the areolar tissue of the limb.

The **Symptoms** occurring after a poisonous snake-bite consist in great prostration, a feeble and intermittent pulse, dilated pupils, usually slight delirium, indistinctness or at times complete loss of speech, speedy stupor, insensibility and death. The pain is burning and lancinating, whilst the part bitten swells and becomes livid in a few hours; and if the patient survive sufficiently long, diffuse inflammation and gangrene occur in its neighbourhood; involuntary evacuations take place: the depression increases and may terminate fatally, or end after a lapse of time in the recovery of the patient, whose health may long suffer from the effects of the accident.

TREATMENT. This is local and general.

The **Local Treatment** can be carried out with success only when the patient is seen immediately after the accident, as the absorption of the poison is very rapid. It presents two great indications: 1, to prevent the absorption of the poison into the system; and 2, to treat the diffuse inflammation and sloughing that may subsequently occur. The first indication may be fulfilled by tying a ligature so tightly round the limb at a little distance above the injured part, as to arrest all circulation through it. In this way the absorption of the poison may be prevented; the wound should then be freely cauterized with a red-hot iron or cinder, or better still, excised, and a cupping-glass applied over the cut surface, so as to withdraw the blood in the neighbourhood which may have become contaminated by the poison. If a cupping-glass be not at hand, or if the part bitten be so situated as not to admit of its application, there can be no objection to the employment of suction by the mouth after free incision; the poison not being absorbed by an unbroken mucous membrane. After using suction, the mouth should be rinsed with brandy. A plan sometimes adopted when the bite is inflicted while shooting in India is to pinch the part up and cut it out at once and then to make a paste in the wound with blood and gunpowder and light it; by this means the raw surface is effectually cauterized. With the view of lessening the swelling, tension, and pain of the limb, frictions with olive oil are said to be advantageous. After diffuse inflammation has set in, this must be treated on general principles—by fomentations and free incision.

The **Constitutional Treatment** consists in the early and free administration of the most powerful *stimulants*, with the view of combating the depression that exists. For this purpose, brandy, wine, ammonia, or ether must be freely given. The *eau de luce*—which enjoys a high reputation in some tropical countries—owes its efficacy to the ammonia which it contains. Should drowsi-

able to walk about; and *artificial respira-*
 tion is resorted to as a last means of maintaining
 life. Patients may overcome those of the poison
 by being made to run for some distance behind a
 horse, or by another means of keeping up the respira-
 tion, such as the elimination of the poison. Large doses of
 opium are used as a kind of specific, and the "Tanjore pill,"
 consisting of its activity to this mineral; but care must
 be taken in giving it, lest the remedy prove as fatal as the
 disease. In cases of bite by the "brown snake,"
 the bite is nearly always fatal, Halford, of Melbourne,
 has used a strong solution of ammonia, diluted with twice its
 quantity of water, in the arterial vein, such as the radial. Fifteen or thirty
 drops are repeated according to circumstances. This is
 said to be causing the patient from his stupor. Sir Joseph
 has used this remedy has no power in cases of cobra-bite, nor
 in cases of Indian serpents, whatever its efficacy may be
 in cases of the effects of those of the Australian species. As
 the virus is changed into a sediment and a supernatant fluid,
 the virus, it might be supposed that it would act as a true
 antidote; but it has been found to do so when injected into the blood of

Exact antidotes for snake-poisoning appears to exist as
 yet. The action as in their discovery. The venom of a snake is at
 first in the blood of the animal bitten, is carried with the circula-
 tion to the centres, decomposing the fluid that conveys it, so that it
 is impossible to find any antidote that can possibly be applied to prevent its direct
 action on the system. It is difficult to understand how an antidote
 could be injected into the veins simultaneously with the intro-
 duction of the snake-poison into the blood. Unless a Surgeon be at hand
 to perform this at the moment, as in the case of an animal bitten for
 the first time, the time lost would probably render the counteraction of the
 antidote. It is evident that drugs or substances swallowed with the
 venom as antidotes could not be absorbed from the stomach in time to

be of any use. Indeed nothing to be done but to endeavour to keep the patient
 alive by the administration of stimulants, until the effects of the poison

RITES OF RABID ANIMALS: RABIES OR HYDROPHOBIA.

In a period of thirty-eight years, ending 1885, 938 deaths are stated to
 have occurred in England and Wales from bites of rabid animals.

Rabies occurs in man only as the result of inoculation from one of
 the animals. It is originally an affection of animals of the canine
 species, the dog, wolf, fox, and jackal, but it is frequently communicated by
 the cat, horse, ass, cow, pig, deer, or sheep. It is generally believed
 that the disease in the dog invariably arises as the result of inoculation from
 a rabid animal, and that it cannot arise *de novo*. This view is supported by
 satisfactory results of muzzling dogs for the prevention of the disease as
 carried out in Berlin and elsewhere, and by the fact that rabies is unknown in

Australia in spite of the large numbers of wild dogs that infest the country, and its introduction has so far been successfully avoided by a prolonged quarantine imposed on all dogs arriving from abroad. That rabies has in rare cases followed the bite of an animal that has shown no definite signs of the disease is believed to be due to the fact that the disease is not invariably fatal in dogs, and may sometimes be so mild as to escape detection. Many circumstances have been supposed to act as predisposing causes of rabies. It undoubtedly appears in epidemics, in some years being scarcely heard of, while in others it is comparatively frequent. The season seems to have some influence on its occurrence, as Eckel found it to be most common in the early spring. Want of water, sudden changes from heat to cold, bad food, and unsatisfied sexual desire, have also been assigned as causes of its development in animals. When we inquire into the operation of these alleged causes, we fail to discover any direct and positive connection between any one of them and rabies. With regard to the influence of heat and want of water, it would appear that in those countries in which animals are most exposed to these conditions, rabies is unknown. Thus, Mr. Donovan, who has resided and travelled for many years in Central Africa, informs me that, in the deserts of that country, where water is so scarce that man and beast often die of thirst, jackals and wild dogs are most numerous, and yet the disease is unknown. The theory of rabies arising from ungratified sexual desire appears to be equally untenable. Having been told that no bitches were allowed in Sark, I wrote to Dr. Cockridge of that island to inquire if this were the fact, and if so, whether rabies were prevalent there. He informed me that there were no bitches in the island, and that the dogs were very numerous, but that no case of that disease had, to his knowledge, ever occurred there, and that the clergyman, who had had thirty years' experience of the island, had never heard of a case. Dogs become rabid more frequently than bitches; thus, of a hundred and forty-one cases collected by Eckel, only fifteen occurred in bitches.

SYMPTOMS IN THE DOG.—The Surgeon is sometimes asked to give an opinion as to the condition of a dog that has bitten a person, and which is suspected of being mad. The following description of the symptoms of **Rabies in the Dog**, by Dr. Burdon Sanderson, will aid him in coming to a conclusion on these points:

"The premonitory indications of rabies in a dog are derived almost entirely from the observation of changes in its demeanour; consequently, although they may be too trifling to be noticed by a casual observer, they are fortunately sufficiently striking to arrest the attention of any one who is about a dog, and is familiar with its habits and individual peculiarities.

"A dog about to become rabid loses its natural liveliness. It mopes about as if preoccupied or apprehensive, and seeks to withdraw into dark corners. From the first there is usually a foreshadowing of that most constant symptom of the disease—depraved appetite. Mad dogs devour not only filth and rubbish of every kind with avidity, but even their own excrement—often immediately after it has been passed. Indications of this tendency appear early, and are more than suspicious.

"Along with this peculiarity of behaviour it is of equal importance to notice that an infected dog, from the first, snaps at other dogs without provocation. This snapshyness in most dogs is very striking. If a dog previously known

to have no such habit, snaps indiscriminately at the first dog it meets in the yard or in the street, it is probably not safe.

"So far I have had in mind chiefly what is to be observed in dogs tied up or at home. A dog which is at large is also to be recognized as in a dangerous state by its demeanour. A healthy dog in its progress along a street or elsewhere, shows at every step that its attention is awake to the sights and sounds which it encounters. The rabid dog, on the contrary, goes sullenly and unobservantly forwards, and is not diverted by objects obviously likely to attract it. This statement, however, is subject to the important exception already referred to, that it is excited both by the sight and sound of an animal of its own species.

"Of the symptoms which accompany the final stage of the disease, the most important and characteristic are those which relate to the organs in which it localizes itself—the mouth and throat. Attention is often drawn to the condition of the mouth in an animal supposed to be healthy, by the observation that it tries to scratch the corners of its mouth, as if attempting to get rid of theropy mucus which is seen to be discharged from it. In dogs that are tied up, it is noticeable that the bark has entirely lost its ring, and acquires a peculiar hoarseness, which can be recognized even by the most unobservant. As the disease progresses the discharge increases, the lower jaw hangs as if paralysed, and the animal has evident difficulty in swallowing. Along with this there is often loss of power in the hind limbs. If now the dog be watched the peculiarities of behaviour which have been already noticed are seen to present themselves in a much more marked degree than before. It is observed first, that it is subject to paroxysms of excitement, in which it makes often-repeated efforts to bite or gnaw all objects (such as woodwork, straw, &c. within its reach, while at the same time it continues to exhibit the tendency already mentioned to devour its own excrement; and, secondly, even during the remissions, its excitement is at once renewed by the sight or sound of another dog.

"It may be well to note that the disease occurs at all seasons, that the mad dog continues to recognize its master, and to manifest pleasure when kindly spoken to, that it does not shun water, and that in many cases from first to last that wild fury which is commonly supposed to belong to the disease, is conspicuously absent."

RABIES IN MAN.—In man, rabies occurs either from the bite of a dog known to be rabid, or from a raw surface, as a crack in the lip, being licked by an animal affected with rabies, but in whom the characteristic symptoms have not developed themselves. The bite of a rabid animal is by no means certain to occasion rabies. The proportion of those bitten by rabid dogs that develop the disease has been variously estimated. Hunter and Vaughan (Halford) put it at only 3 to 5 per cent., while Leblanc, from statistics collected in Paris, makes it 16 per cent. Ruffier, from the consideration of a large number of statistics, assumes the proportion to be 15 per cent. The bite of a rabid wolf is far more dangerous, no fewer than 67 per cent. of those bitten dying of the disease. The bite of a cat also is more dangerous than that of a dog. The fact is that the dog usually bites at the legs, and then when he inflicts a wound, it is through clothing, by which his teeth are wiped and the saliva arrested, and thus the wound escapes inoculation. Wolves and cats, on the other hand, always fly at naked parts of the body, as the face of

throat; hence the greater danger of their bites. There is this important difference between the poisonous inoculation of the wound by the bite of a rabid dog and of a snake. In the case of the dog the poison is only adherent to the tooth, and hence, if this be wiped in its passage through clothing, the bite is rendered innocuous. In the case of the snake, the poison is projected through the hollow fang, and hence, wherever that enters, however clean its exterior may be wiped, this drop of poison is injected into the parts at the extreme point of penetration. But making all allowance for the mechanical action of clothing in preventing inoculation of the part bitten, there is, I think, good reason to believe that there is a great difference in the susceptibility of different individuals to the poison of rabies. For it is an undoubted fact that veterinary Surgeons and others have often been bitten on an uncovered hand by rabid dogs, and yet have escaped the disease. Elliotson mentions the cases of two sisters who were both bitten on the face by the same rabid dog; the first escaped, the second died of rabies. White, of Brighton, disbelieving in the contagion of the disease, inoculated himself with the saliva of a rabid dog with impunity.

Nothing is as yet known as to the exact **nature of the virus**, and all attempts to discover a specific micro-organism in the infective secretions and tissues have so far failed. The observations of Pasteur seem to show that its activity is abolished by drying, heat, and putrefaction, but can be preserved for some time by cold and moisture. The virus exists in the saliva and salivary glands, in the central nervous system, and in the peripheral nerves, but no satisfactory proof has been given that it exists in the blood.

Period of Incubation.—Rabies differs from most other specific diseases in the length of time that the poison may lie dormant without giving rise to any symptoms. This period is very variously estimated by different writers. It is said to have been as short as three days and as long as fifteen years, but it is now generally believed rarely to extend beyond a few weeks. In only 6 per cent. of 147 authentic cases was it found to exceed six weeks. Ruffer adds that in 97 per cent. of fatal cases, death took place within four months of the bite. In the case of the Duke of Richmond, who was bitten whilst separating a tame fox and a dog that were quarrelling (it is doubtful by which animal the bite was inflicted), the disease did not develop itself for six or seven weeks. Meade has related the case of a lady who had the disease fifteen months after the bite; and Mayer, of St. Petersburg, that of a young man who died of rabies twenty-six months after being bitten; Sir Thomas Watson adduces evidence that the poison may lie dormant for years. Writers, however, who state that six, seven, twelve, and even fifteen years have intervened between the infliction of the wound and the manifestation of the symptoms, have evidently fallen into error, having probably confounded with hydrophobia other nervous affections that closely resemble it. In this long and uncertain period of incubation the disease bears some resemblance to syphilis, which may occasionally give rise to no definite symptoms, either local or general, till six weeks after inoculation.

Symptoms in Man.—The wound has generally cicatrized long before any symptoms of rabies declare themselves; and no peculiar appearance is produced by the scar. Shooting pains, twitching and itching sensations have, however, occasionally been experienced in the site of the wound before the onset of the disease.

The symptoms are usually ushered in for two or three days (according to Perry for five or six) by some antecedent phenomena, consisting of giddiness, chills and heats, and a general feeling of discomfort, whilst often the onset is marked by great depression with irritability of temper. In some cases vesicles under the tongue have been observed. The more *special* symptoms never manifest themselves until the disease is fairly established: they consist essentially in violent and repeated convulsive movements of a reflex character, induced by various external influences acting on the surface of the body or on the fauces, or by mental impressions; and they speedily end in exhaustion and death. At an early stage of the disease the knee-jerks are exaggerated.

The special symptoms are referable to an excessive irritability of the medulla and upper part of the cord, in consequence of which the slightest afferent impulse causes a wide-spreading and violent reflex spasm of the muscles of deglutition and respiration, and of those of the neck and sometimes of the jaw and tongue. At the same time there is considerable mental disturbance, chiefly assuming the form of excessive terror and agitation.

The *Excessive Irritability of the Medulla and upper part of the Spinal Cord* is shown first by the very slight nature of the afferent impulses which are sufficient to cause a reflex spasm. A blast of cold air, the rustling of the bed-clothes, the slightest touch or movement on the skin, will bring on convulsions. As the disease advances, stimulation of the nerves of special sense produces the same effect: so that a sudden flash of light, as the reflection of the sun from a looking-glass, or a sudden noise, as the slamming of a door, will bring on a spasm. Mental impressions even may cause the same result. The noise produced by liquids being poured from one vessel to another is peculiarly distressing to the patient; and Elliotson mentions a case in which a patient with rabies was thrown into violent agitation by hearing the dresser who sat up with him void urine. The sufferings and convulsions which the patient experiences when he attempts to drink are owing to the same cause. The normal reflex contraction of the muscles of deglutition that occurs in swallowing becomes spasmodic, and spreads widely to other muscles, ending in a general convulsion, and the recollection of these sufferings makes him afraid to repeat the attempt; hence the fear of liquids, from which the name "hydrophobia" is derived.

In the earlier stages of the disease the spasm affects chiefly the muscles of deglutition and respiration: a catch in the breathing, resembling what often occurs when a person goes into a cold bath, is met with as one of the earliest symptoms, taking place in the midst of conversation, and before the patient's mind is directed to the nature of the disease. This catch is due to the spasmodic descent of the diaphragm, and gives rise to severe pain at the pit of the stomach, or to a feeling of suffocation. In consequence of this spasm of the diaphragm, the patient makes from time to time a loud hiccuping noise, which has been likened to the bark of a dog. As the disease advances these spasms extend more widely, and increase in violence. The extraordinary muscles of respiration and those of the neck and jaw are thrown into violent spasms, and the convulsions may extend even more widely. The laryngeal muscles also become affected, and spasm of the glottis is not an uncommon mode of death. Towards the end of the case the spasms may occur without any recognizable external stimulus, but just before death they may entirely cease.

From an early stage of the case there is an abundant viscid secretion from

the mouth and fauces, which the patient finds great difficulty in expectorating, often trying to pull it out with the fingers; and children may in this way scratch and tear the skin of the lips and nose.

One of the earliest symptoms, and one of the most persistent, is extreme *Mental Agitation and Terror*, a vague sense of dread and horror at the impending fate. Spectral illusions sometimes occur, the patient supposing himself to be surrounded by animals, by horrid forms, by gaping, ghastly, and grinning countenances, or by flies or wasps. The first symptom in the Duke of Richmond's case was that he fancied some poplar-trees opposite his bedroom-window to be men looking in. These delusions may alternate with fits of delirium, terror, and frenzy. In these it is said that the patient barks like a dog, and endeavours to bite; but this is a popular error—the "bark" is merely the catch in breathing, and the attempt to bite is nothing but movements of the tongue and mouth induced by the viscid saliva.

The temperature is not usually much over 100° F. Albumen and sugar have been found in the urine by F. A. Southam, the sugar doubtless depending on irritation of the medulla oblongata.

Gamalela, Bristowe and Horsley, and others have recorded cases of rabies in man assuming the paralytic form, which is the variety usually occurring in rabbits and occasionally in dogs—"dumb rabies." The disease then proves fatal from ascending paralysis.

Duration and Termination.—The disease may prove fatal in four-and-twenty hours, or life may be prolonged for six or seven days. Death generally takes place from the second to the fourth day, and may occur from spasm of the glottis or from exhaustion. Occasionally the symptoms subside completely before death; the increased sensibility of the surface disappearing, the mental agitation or delusion being removed, and deglutition and respiration being quietly performed. Thus, Latham relates the case of a man labouring under this disease, who sat up quietly in bed and drank a pint of porter half an hour before he died. In these cases the pulse gradually becomes slower and slower, and finally ceases. This mode of death is not exhaustion, but is due to a destructive change in the cardiac centre in the medulla.

Prognosis.—I am not acquainted with any case of recovery from rabies, and, when once the first symptoms have made their appearance the disease seems to be invariably fatal.

Pathology.—The appearances which are found after death in undoubted cases of rabies harmonize with the symptoms observed during life. The most definite and characteristic change is found in the lower part of the medulla, "most intense in the hypo-glossal, glosso-pharyngeal and vagal nuclei and their neighbourhood." Gowers found the changes identical and clearly marked, that the nature of the affection could have been recognized from the *post-mortem* appearance alone in seven out of eight cases he examined. Nothing is visible to the naked eye, but the microscope shows *ante-mortem* changes in some of the minute vessels, and the perivascular spaces in the affected region are crowded with leucocytes. In the regions in which the disease is most advanced, the leucocytes pass beyond the lymphatic spaces and invade the tissues of the medulla, sometimes being so closely packed as to conceal the normal structures in minute spots. The only change in the nerve elements is slight granular degeneration. The appearances are, in short, those of inflammation of the affected region. These appearances were well

demonstrated by Marcus Beck in a case which occurred in University College Hospital in 1871. Benedikt and others have found identical changes in the dog. Taking the *post-mortem* appearances and the symptoms together, it appears probable that the essential feature of the disease is an infective inflammation, chiefly affecting the medulla oblongata. The first sign of damage to the nerve-elements is their loss of resistance, and the occurrence of violent and irregular action from slight causes. If the patient does not perish at an early stage from exhaustion, damage of the nervous tissue progresses till it comes to respond more feebly than natural to the different impulses it receives: this corresponds to the period of calm that so frequently occurs before death. Finally, it becomes incapable of performing its functions, and the heart ceases to beat. Coutts states that he has found, in addition to the congestion of the fauces always met with, actual infiltration of the salivary glands with leucocytes. Beyond these no definite appearances are met with. Although Pasteur has not been able successfully to inoculate the blood of a rabid animal, there is no doubt that the virus can be carried to the brain and cord by the circulation. To prove this he inoculated a rabbit by injection into the auricular vein and immediately afterwards cut off the ear, but the symptoms developed as usual. The theory that the virus can reach the nervous centres by direct extension along the nerves has nothing to support it.

Rabies belongs to the class of specific infective diseases, its chief peculiarity being the unusual duration of the period of incubation. It is in no way more extraordinary than such a disease as mumps, in which a period of perfect health, lasting for three weeks, intervenes between infection and the appearance of a local acute inflammation attacking the parotid gland.

TREATMENT.—This must be principally *preventive* and *palliative*. We cannot speak of *curative* treatment of rabies; for, after the disease has once set in, the utmost that can be done is to lessen the patient's sufferings, and delay for a few hours the almost inevitably fatal termination.

Preventive Treatment.—From what is known regarding the nature and mode of spread of rabies, it appears certain that much can be done by State regulation to exterminate the disease. The most important measures are: 1. The destruction of all dogs which are rabid or suspected of being so. 2. Seizure of all ownerless and wandering dogs. According to Fleming, 249 out of 601 rabid dogs were returned as stray ones. 3. All dogs to be efficiently muzzled while rabies prevails, and for some time afterwards. The efficacy of muzzling has been amply proved; in 1885 twenty-seven deaths from rabies occurred in London, whilst in 1886, after the muzzling order was enforced, no death was recorded. 4. The registration and taxation of all dogs. Owing to the fact that but a small proportion of those bitten are attacked by the disease, innumerable popular remedies have obtained an unmerited reputation for preventing rabies.

When a person is bitten by a rabid dog, or by one that is reasonably suspected of being so, the Surgeon should always adopt energetic means to save the patient from so fatal a disease. As soon as possible after the bite has been inflicted, a string or bandage of some kind should if possible be applied on the proximal side of the wound, so as to arrest the circulation. Suction is commonly recommended, and would be almost instinctively practised; but it is not altogether devoid of danger, as there is reason to believe that inoculation may take place through the mucous membrane of the lip and mouth, and this

would certainly occur if there were any crack or abrasion. The only preventive means that can be trusted are *excision* and *caustics*.

Excision is no doubt the most effectual preventive treatment, but it is seldom practised. It should be freely performed, no half measures being had recourse to. It is better to remove too much of a comparatively unimportant tissue or part, than to allow the sufferer to run any risk of falling a victim to the fatal disease. In order to excise every part that has been touched by the tooth, the Surgeon should pass a probe to the bottom of the wound, and excise the whole by scooping out a conical piece of the tissues, taking care to go beyond the furthest limit to which the probe is passed. If there be any doubt of the removal of the whole of the injured parts, a caustic should be applied. If the lip be bitten through, a portion may be cut out, and the wound brought together, as in hare-lip operations; if a finger be injured, it may be amputated.

Caustics are much more commonly used. The introduction of a sharp-pointed stick of nitrate of silver into each tooth-mark was strongly recommended by Youatt, who had himself been bitten twenty times. Potassa fusa is also a most efficient caustic, but it is apt to extend its action farther than is intended. Liquid caustics poured into the hole left by the tooth have the advantage of penetrating very thoroughly into every part of the wound. Pure carbolic acid, or fuming nitric acid, may be used in this way. If the wound have already cicatrized, the bitten part may be excised at any time after the injury, provided the dog is known to have been mad, or to have become so afterwards: for it is not impossible that, in the cases in which the disease has occurred at a remote period, it has been dependent upon, or connected with, some peculiar action set up in the wound, which might possibly be averted by the removal of the cicatrix.

Pasteur's Preventive Treatment.—In 1880 Pasteur commenced a series of researches into the nature of rabies, as the result of which he believes that he has discovered a means of rendering an animal incapable of developing the disease if inoculated with the virus, and that within certain limits of time he can, by the same treatment, prevent the occurrence of the disease, even after inoculation of the virus on an unprotected animal. He started with the idea that it might be possible so to attenuate the virus that its inoculation might induce a modified form of the disease, free from danger to life, but protecting the animal from a subsequent attack. In this he was not successful, and his present mode of treatment, although conferring immunity, produces no appreciable disturbance of health. In this it differs mainly from vaccination. It is impossible to give here more than the briefest summary of Pasteur's work. The first definite result arrived at was the fact that the virus is constantly present in the central nervous system of rabid dogs, and can thus be obtained free from contamination by the septic organisms always present in the saliva. By crushing up portions of the cord in sterilized broth a suitable material was obtained for inoculation, and it was found that by trepanning an animal and injecting the virulent fluid beneath the arachnoid, rabies can be induced with perfect certainty, and that the incubative period is reduced to from six to ten days. Pasteur next found that by inoculating a series of monkeys, using the cord of the first for the second and so on, a gradual attenuation of the virus takes place, until its virulence disappears entirely. By inoculating the attenuated virus he succeeded in producing immunity in dogs. Further observations showed that by inoculating a series

of rabbits with the attenuated virus from monkeys he could gradually restore and even increase its virulence; the chief evidence of the increased virulence being the gradual shortening of the incubative period. At last by passing the poison derived directly from a dog through a series of rabbits he obtained apparently the maximum virulence, inoculation by trephining being certainly followed by rabies on the seventh day, and at this point the intensity of the poison remained constant. The symptoms in the rabbit differ somewhat from those in the dog, the most marked feature being paralysis of the hind legs, gradually extending to the fore legs before death. After death the whole length of the cord is equally virulent. That the disease thus induced is true rabies is proved by the fact that dogs inoculated with the rabbit's cord develop the typical disease either of the dumb or the furious variety. The virus of constant strength having been thus obtained, the next point is to attenuate it so that it can be inoculated without a fatal result. The means of so doing was found in simply drying the cord. If the cord, removed with all practicable antiseptic precautions, be suspended in a glass-jar, at the bottom of which some caustic potash is placed to dry the air, its virulence gradually disappears until at the end of from 10 to 14 days it is completely lost. Pasteur inoculated dogs with this attenuated virus in the following way:—Every day a portion of cord rubbed down in sterilized broth was injected beneath the skin, commencing with some that had been dried long enough to have lost its virulence, a more virulent material being used each day till at last the fresh cord was reached. It was found that this could be done without disturbing the health of the dog, and at the end of the process the animal presented a perfect resistance to the most intense virus, nor could rabies be given to it by the bite of a rabid animal. That Pasteur and others have thus conferred upon dogs a perfect immunity to the virus of rabies cannot be doubted, but how it is done is quite uncertain. Pasteur asserts that the poison, whatever it may be, is destroyed by drying, and that it is not a true attenuation but rather a diminution in quantity that takes place as the cord dries. Although no organism has yet been found, Pasteur suggests that one may be present which produces in its growth a chemical substance hostile to its own development, a condition met with in numerous organised ferments. In the dried cord the living organism perishes gradually while the chemical antidote undergoes no change. This is, of course, merely a hypothesis.

On July 6th, 1885, Pasteur first applied his method to the human subject. The patient, Joseph Meister, aged 11, had been severely bitten in fourteen places by a mad dog. The boy suffered no evil effects from the treatment, and is still alive and well (1893). Since that time thousands have flocked to Pasteur's laboratory from all parts of Europe, and some even from America, and institutions have been founded in Budapest, Odessa, Turin, etc., where the treatment is carried out.

The treatment has been modified in some points, but the following may be taken as an example of the way in which it is carried out. The cord is pounded up with a glass rod in a quantity of sterilised veal broth equal to four times its bulk before it was dried, and of this mixture one, two, or three cubic centimetres are used in each inoculation. The injections are made under the skin of the abdomen once or twice a day. The following numbers indicate the days of drying to which the cord has been submitted at each injection:—First day, 14, 13; second day, 12, 11; third day, 10, 9; fourth day, 8, 7,

fifth day, 6; sixth day, 5; seventh day, 5; eighth day, 4; ninth day, 3; tenth day, 5; eleventh day, 5; twelfth day, 4; thirteenth day, 4; fourteenth day, 3; fifteenth day, 3.

The "intensive" treatment is adopted in wolf-bites and the more severe cases of bites from undoubtedly rabid dogs. In these cases the injections are continued during twenty-one days, whilst the early injections are more numerous, so that a cord dried for six days is used on the third. No abscesses or other local troubles beyond a little tenderness and redness have in any case followed the injections.

That the treatment is not infallible Pasteur himself acknowledges: how fallible it is can scarcely yet be determined. From 1886 to 1892 inclusive, 12,744 persons underwent the antirabic treatment at the Pasteur Institute; of these 112 died, showing a mortality of 0·88 per cent. These cases are arranged in three classes: first, those bitten by animals proved by experiment to be rabid; secondly, those bitten by animals certified to be rabid by veterinary Surgeons; thirdly, those bitten by animals suspected of rabies. Of the total number treated, 10,298 had been bitten by animals proved or certified to be rabid: 95 of these died, giving a mortality of 0·92 per cent. Excluding these cases which have proved fatal from rabies during the treatment or within fifteen days of its termination, only 72 deaths have occurred in the 14,430 cases treated up to the end of 1893; this gives a mortality of only 0·50 per cent. This must be compared with the mortality of 15 per cent. which follows the bites of rabid animals treated by other methods. It can thus hardly be denied that the treatment has been productive of a great saving of life. In a considerable number of other institutions founded for the purpose of carrying out Pasteur's treatment the results have been equally satisfactory. No cases are on record proving that death has resulted from the treatment, and it is probable that those few instances in which paralysis ending fatally occurred during the "intensive" treatment were cases of "paralytic rabies."

A committee, composed of Sir H. Roscoe, Dr. Burdon-Sanderson, Sir James Paget, Sir Joseph Lister, Dr. Lauder Brunton, Dr. Quain, Dr. Fleming, and Mr. Victor Horsley, was nominated by the President of the Local Government Board in 1886 to inquire into Pasteur's treatment, and after a most exhaustive investigation, as a part of which Horsley repeated the experiments on animals, the committee reported in 1887, fully confirming Pasteur's conclusions on every important point.

The treatment can of course be carried out only in institutions established for the purpose, as it is necessary to keep a large number of rabid rabbits constantly in stock, for if from any cause the intensified virus as developed in the rabbits died out it would take some months to develop it again by a fresh series of inoculations starting from a rabid dog.

The treatment may be commenced at any time before the invasion of the disease, but the chances are of necessity very seriously diminished after a fortnight from the date of the bite.

Palliative Treatment.—After the disease has once set in, nothing can be done but to *palliate symptoms* and prolong life. Every possible remedy that the ingenuity of man could devise, from warm water to viper- and toad-poison, has been tried and found utterly useless.

But, although no treatment hitherto tried has been successful in curing this horrible disease, much may be done to mitigate the sufferings caused by

it. All sources of external irritation, whether physical or mental, should be removed. The patient should be placed in a darkened and quiet room, and not subjected to the intrusive curiosity of strangers; and the bed should be surrounded by curtains or screens, so as to prevent the disturbing influence even of a draught of cold air blowing on the surface. Chloroform may be administered by inhalation, or chloral may be injected subcutaneously in 10 to 15 grain doses every second or third hour, in order to calm the violence of the spasms and to procure sleep, but care must be taken not to push it too far lest coma result.

In a case lately in University College Hospital the patient experienced great relief from having the fauces occasionally brushed with a solution of cocaine.

The hot air or vapour bath often affords great temporary relief, and diminishes in a marked manner the violence of the spasms.

The subcutaneous injection of curare has been strongly recommended, and doubtful cases of cure by its means have been reported. The dose is from $\frac{1}{4}$ th to $\frac{1}{2}$ th of a grain every third hour. Mercury pushed to salivation was formerly recommended both as a preventive and a curative treatment. Andry (1779) relates numerous cases, apparently authentic, in which it seems to have been of use. Tracheotomy has been recommended in order to avert death by spasm of the glottis. But what possible good can result from preventing death by this cause when it is impending from another? Lastly, the Surgeon must bear in mind that he has to treat an exhausting disease, and that he must consequently support the patient by wine, beef-tea, and such nourishment as can be taken.

MALIGNANT PUSTULE.

Malignant pustule or charbon is the name commonly given to the affection produced by the inoculation, on the cutaneous surface in man, of the virus of the disease of cattle known as splenic fever or anthrax. Splenic fever is fortunately rare amongst animals in this country, while in France and some parts of Germany it occurs with considerable frequency amongst horned cattle, horses, and sheep. Malignant pustule is consequently also rare here, being met with chiefly amongst workers in foreign hides or wools; on the Continent it is common also amongst butchers. The virus has now been clearly proved to be a large, easily recognisable microscopic organism, the bacillus anthracis. It may find entrance into the body by the lungs or intestines in the form of dust, and then it gives rise to a general disease running a rapid and fatal course without the formation of an external centre of inflammation. This affection, which is known as "wool-sorters' disease," was brought prominently into notice by the occurrence of several fatal cases at Bradford amongst workmen engaged in sorting Persian and Bokharan wools. Malignant pustule assumes an importance quite out of proportion to the frequency of its occurrence: first, because of the necessity of recognising it early for its successful treatment; and secondly, because it forms a type of a true infective process, both local and general, and its exact pathology is better understood than that of most other diseases of the same kind.

Symptoms.—The first symptom of malignant pustule is the formation of a small angry red pimple on some exposed part of the body—either the face, hands, or arms. The patient may be conscious of having scratched or pricked

himself at the point at which the pimple appears, or he may rightly or wrongly attribute it to the bite or sting of an insect. The pimple is accompanied by intense itching, and after some hours a vesicle forms on its summit, which is burst by the patient's scratching it. There now forms a distinct indurated patch, which rapidly extends; at first it is grey in colour, but by the end of the second day the central part is black. The skin in the neighbourhood becomes red and swollen, and round the edge of the black patch a ring of vesicles is formed. The individual vesicles are about the size of mustard-seeds. There now follows considerable swelling of the surrounding parts with enlargement of the neighbouring lymphatic glands, and if the pustule is seated on the arm, red lines may run up towards the axilla. The rate of progress varies considerably, but by the fifth or sixth day the black eschar may attain the size of a florin, and the surrounding swelling may affect the whole side of the face or the greater part of the arm. Beyond the itching there is but little pain. The constitutional symptoms are not severe at first, but by the fourth or fifth day the temperature rises to 101° or 102°, the pulse becomes quick and irregular, the tongue dry, and the patient suffers from headache and a feeling of general severe illness. There may be dyspnoea or fainting, diarrhoea, and occasionally delirium. If no treatment be adopted, the case most frequently terminates fatally in less than a week from its commencement. The whole process may, however, remain local and cease of itself, the redness subsiding, the slough separating, and the resulting granulating sore healing with considerable disfigurement. This favourable termination is, however, very rare.

In some exceptional cases, the result of the inoculation may be a widely diffused cedema without the formation of a distinct localized inflammation. This form is rapidly fatal. If the patient survive beyond three or four days, eschars and pustules may form in the swollen part. This form has been described by the French writers under the name of "*malignant cedema*."

The internal form—"woolsorters' disease," or, as it has been called, *anthraxæmia*—belongs rather to the Physician than to the Surgeon. The disease begins with a great sense of illness—sometimes with a rigor—vomiting, and headache, followed by high fever, marked dyspnoea, and coldness of the extremities; usually fatal collapse rapidly ensues. It may assume a pulmonary form, in which the symptoms resemble acute pneumonia or bronchitis; or an intestinal form, in which vomiting and purging are marked features. The whole illness may last less than two days, or may be prolonged to four or five. Woolsorters' disease is extremely fatal.

The **diagnosis** of malignant pustule is not difficult when the characteristic features are well developed. The black eschar, surrounded by vesicles, around which again is a bright red zone, and the wide-spreading cedema are characteristic. If there is any uncertainty, microscopic examination of the blood or inflammatory exudation will clear up the doubt.

Pathology.—After death from malignant pustule, the body presents the appearances usually met with in cases of malignant blood-poisoning. Rigor mortis is of short duration and feebly marked, there being frequently early decomposition and marked *post-mortem* staining of the tissues. The blood is dark in colour, and imperfectly coagulated, and minute extravasations of blood are found beneath the serous and mucous membranes throughout the body. There is swelling of most of the abdominal viscera, but the spleen,

especially in the lower animals, shows the greatest change: it is swollen, black in colour, soft, sometimes almost diffuent; the mucous membrane of the stomach and intestines is frequently redder than natural, and may be marked by patches of hæmorrhage. The lungs are usually gorged with blood, especially at their bases.

Locally it is found that the eschar is hard and dry, and penetrates deeply into the subcutaneous tissue, but not beyond. The neighbouring lymphatic glands are enlarged and redder than natural.

Microscopic examination of the local lesion, of the blood and of the viscera shows everywhere the presence of a microscopic organism of considerable size—bacillus anthracis (Fig. 113). This organism was discovered by Pollender as long ago as 1849, but its complete life-history and its definite relation to splenic fever have been more recently worked out by

Davaine, Chauveau, and Pasteur in France, Koch in Germany, Klein, Ewart and Greenfield in this country, and a multitude of other observers. The bacillus anthracis is a rod-shaped organism, varying in length from $\frac{1}{1000}$ to $\frac{1}{250}$ of an inch, and of an average breadth of about $\frac{1}{8000}$. Thus in human blood the length of the bacilli may reach between two and three times the diameter of a red corpuscle, and their width to about one-quarter of its thickness. The organism is abundantly present in the diseased skin and in the blood in "malignant pustule" in man. In the affected skin it shows a marked predilection for the most superficial parts of the papillary layer of the cutis immediately beneath the rete Malpighii, as shown by Barker in a case which

Fig. 113.—Bacillus Anthracis in Lung.

occurred in University College Hospital. By cultivating it in suitable fluids out of the body its mode of growth can be observed. It multiplies when growing actively by increasing in length till it reaches a certain size, and then dividing by fission at or near its middle. When growing in this way the filament remains homogeneous in structure throughout; it is easily destroyed by exposure to a moderate degree of heat, and by carbolic acid and all other chemical antiseptics. The length of the filament as compared to its breadth varies considerably according to the medium in which it is cultivated. When grown on solid media (nutrient gelatine, agar-agar, or potato), with free access of air, spore-formation takes place, and the same will happen in fluid media if the organism for any reason floats on the surface. The spores appear as minute highly refracting dots, in the protoplasm of the bacillus. After they have formed the organism may break up, leaving only the spores, surrounded by a little jelly-like material; or the spores may be quite free, or still situated in very short segments of the original rods. It has been proved by experiment that under

proper conditions these spores grow into the fully-developed bacilli—that they are really genuine germs of the fungus. From their extremely small size it is evident that if dried they could without difficulty be transported from one place to another as dust in the air, and it is, in fact, these dried spores that serve as the poison both in malignant pustule and woolsorters' disease as seen in this country. Wurtz and Lodge have cultivated the bacillus from the dust of a rag-warehouse in Bradford, in which a worker had contracted pulmonary anthrax. The power of resistance of the spores to injurious influences is so great as to render the task of disinfection after splenic fever undoubtedly difficult. The experiments of Robert Koch have shown that blood containing spores of the bacillus may be dried, and even allowed to putrefy in drying, and kept afterwards for years without losing its virulence. The spores may be exposed to a moist heat of 212° F. for a very short time, or to a dry heat for a longer period, without injury. Alcohol, glycerine, watery solutions of carbonic acid (1 to 20), salicylic acid, thymol, and weak solutions of permanganate of potash are equally powerless to destroy their vitality. On the other hand, freshly prepared chlorine-water, bromine (2 per cent. solution), iodine, perchloride of mercury (1 in 5000 in water), or permanganate of potash (5 per cent. in water), destroy their vitality. This extraordinary resisting power is fortunately shown only by spores, and as far as we know the ordinary bacteria of putrefaction and all micrococci, whether septic or pathogenic, multiply only by fission, and are, like the bacillus when not in the spore-bearing stage, readily destroyed by heat and chemical antiseptics.

That the organism is the actual cause of the disease is proved by the fact that when the bacillus is in the spore-bearing stage it may be washed with distilled water, alcohol, and ether, and then dried, and after all this, if inoculated, it is capable of producing splenic fever in the animal experimented on. After inoculation it produces its local effects probably by setting up chemical changes of a fermentative character in the fluids of the part, giving rise to intensely irritating products, which, by a process analogous to cauterisation, cause inflammation, and, sinking into the surrounding lymph-spaces, give rise to the spreading œdema and inflammation beyond the area in which the organisms are actually growing. When the bacilli get into the blood and grow widely throughout the body, they are supposed to act partly by causing mechanical obstruction of the capillaries, and partly by robbing the blood of its oxygen; for, like all fungi, they absorb oxygen during their growth. This would account for the dyspnoea and cyanosis usually met with before death from malignant pustule.

Pasteur, from numerous experiments, came to the conclusion that if the bacilli are cultivated in a fluid medium at a temperature of from 107°6 F. to 109°4 F., they do not form spores, and if grown in this way for about twenty days they become less virulent, or, as it is termed, the virus is attenuated. In this state if inoculated on a sheep they give rise to a modified form of splenic fever which is not fatal, and Pasteur affirms that after recovery from this the animal may be inoculated with the most intense virus with impunity. The analogy between this process and vaccination gave a peculiar interest to Pasteur's observations, and numerous observers have repeated his experiments with the result of generally confirming his statements that the virus may be attenuated by various means, and that if inoculated in this form it produces a power of resisting the infection of splenic fever, lasting from nine

months to a year. The attenuation of the virus may be brought about in various ways. Thus Klein states that the blood of a sheep dead of anthrax will invariably cause death if inoculated on a sheep, but if the disease be communicated to a white mouse the blood of that animal, although teeming with bacilli, only causes a transitory illness in a sheep, and leaves it, for a time, protected against the virulent form of the disease. Klein has also shown that the virus may be attenuated by being acted on by very dilute solutions of perchloride of mercury, and that if inoculated in this form on sheep it will produce a modified form of the disease which will protect them from virulent anthrax. It has also been shown by J. T. Cash that the rabbit, which is an animal very easily infected with anthrax, may be protected from the action of the most intense virus by preparing it for some days before by the hypodermic administration of perchloride of mercury in as large doses as it can bear.

One other point may be briefly noticed. Sidney Martin has shown that the bacillus anthracis produces by its growth in artificial culture media, and in the living body certain definite chemical products. These are albumoses—anthrax proto- and dentero-albumose—and a basic body, provisionally called an alkaloid. In small doses the albumoses produce fever, and in large doses local oedema and coma. The basic body on the other hand, produces, even in small doses, coma ending in death, and often enlargement of the spleen. These observations are obviously of the greatest importance; but the exact relation of the chemical products to the production of immunity is still uncertain. Martin has, however, shown that Pasteur's vaccine contains both the albumoses and the basic body, whilst Hankin believes that immunity can be produced by the albumoses alone.

It is needless to point out the important bearing of these observations upon numerous questions of pathology and therapeutics, such as infection in general, vaccination, modification of diseases by passing through different animals, changes in form of micro-organisms according to the medium in which they are grown, disinfection, antiseptics, and the influence of mercury on infective processes, &c. The whole subject of anthrax and the bacillus anthracis is one that will well repay the time spent in a thorough study of it. It is impossible to make here more than a passing allusion to the work that has been done.

The *Treatment* of malignant pustule must be energetic and active; no half measures are likely to be successful. The whole indurated area of the skin should be removed with the knife, and to the raw surface thus left some powerful antiseptic should be applied; perhaps the best would be a strong solution of iodine, which has been shown by Koch to be capable of destroying even the spores of the bacillus.

In London, malignant pustule has been most frequently seen at Guy's Hospital, as the chief part of the hide trade is carried on in the neighbourhood of that institution; during a period of ten years seventeen cases came under the care of the Surgeons. The treatment by excision was employed in fifteen cases, and of these all but two recovered. The favourite application after excision was chloride of zinc, either in a strong solution or as a paste. Davies-Colley, who reported these cases in the Transactions of the Medical and Chirurgical Society for 1882, states that "it is very important to remember that, even after the swelling has extended to a considerable distance, and the adjacent glands have been affected, and after well-marked symptoms of blood-poisoning

have developed themselves, the patient may be restored to health by the removal of the indurated area of skin which was primarily attacked."

GLANDERS.

Glanders is a virulent disease, communicable by contagion to man from the horse, ass, or mule. In spite of the intense contagiousness of the disease and the frequency with which it occurs among animals of the equine species, it is rarely met with in man.

The poison of glanders gives rise to two forms of disease in the horse, one known as *glanders* proper and the other as *farcy*.

Glanders in the Horse almost invariably runs a chronic course. The first symptom is a thin watery discharge from the nose, which, as the disease progresses, becomes viscid and tenacious; lastly, it becomes purulent, offensive, and mixed with blood. The inflammation extends through the whole nasal cavity and frontal sinuses, and is accompanied by ulceration. There is also marked swelling of the lymphatic glands under the jaw. The disease may exist for some time without seriously impairing the health of the animal, but gradually loss of appetite and strength, emaciation, and cough set in, and death takes place from exhaustion. Before death the disease always becomes complicated by the second form or *farcy*.

Farcy is characterised by swelling of the lymphatic glands in various parts of the body, especially on the inside of the thighs, and under the fore leg. The lymphatic vessels leading to and from the glands become inflamed, forming hard, tender cords with swellings opposite the valves. These form the "corded veins" and "farcy-buds" of the farriers. The swellings opposite the valves enlarge and become adherent to the skin, and finally ulcerate, forming foul sores. The disease may at any time become complicated with acute glanders. Acute glanders is merely a great exaggeration of all the symptoms with high fever, hurried respiration, and cough.

The *post-mortem* appearances of glanders in the horse are a dark redness and swelling of the pituitary membrane, with numerous small white elevations and patches, softening in the centre so as to form ulcers. A similar condition extends to the mucous membrane of the bronchi. In the lungs are numerous consolidated patches, varying in size from a millet-seed upwards, opaque yellow in colour, and softening in the centre, sometimes having the appearance of minute abscesses. With these may be patches of pneumonia. Gamgee describes as occasionally present in the lungs large masses of a bluish-white colour and lardaceous appearance, sometimes as big as a hen's egg. Subserous patches are common.

Glanders and Farcy in Man usually occur together and run an acute course, although occasionally they may become chronic. The disease is always communicated by inoculation, usually into a scratch or other wound; but cases have been recorded in which it seemed to have been communicated through unbroken mucous membrane. The inoculation is followed by a period of incubation, which is said to vary from two days to two weeks. The invasion is marked by fever and a great sense of illness. There may be rigors, vomiting, and diarrhoea. In some cases there have been such severe pains in the limbs that the disease has been mistaken for rheumatism. The seat of inoculation becomes inflamed, and the nearest lymphatic glands

become enlarged and tender. Inflamed lymphatic vessels, with hard knots opposite the valves, may also be present. At a period after invasion varying from two days to a week or more, a characteristic eruption makes its appearance. This consists at first of red spots like flea-bites, which soon assume the form of elevated yellowish tubercles situated in the structure of the true skin or immediately beneath it. From their shot-like feel they may at first resemble the early stage of small-pox pustules, but they are not umbilicated and are more deeply situated, as shown by Boyd. They soon soften, forming minute abscesses in the cutis vera, the contents of which are at first hemorrhagic. They then burst, leaving small yellowish ulcers discharging a thin purulent fluid. Together with these there may also be a vesicular eruption. There soon sets in an offensive discharge from the nose, at first watery, but afterwards puriform, and the lymphatic glands under the jaw enlarge. Finally, subcutaneous abscesses form in various parts, which may be accompanied by hemorrhages into the muscles and intermuscular tissue: pneumonia or pleurisy may occur before death. Abscesses may be found in internal organs, as the liver or lungs. The final stages resemble pyæmia in many respects. Throughout the case the constitutional symptoms are of the gravest kind. There are great depression, high fever, delirium, and rapid emaciation. In some exceptional cases the disease may run a very chronic course.

Diagnosis.—The disease may resemble rheumatism before the eruption appears, but the appearance of the latter soon clears up the case. The eruption, as before stated, somewhat resembles that of small-pox, but the general symptoms of this disease are wanting. The history of the association of the patient with glandered horses is an important element in the diagnosis. As a means of diagnosis in doubtful cases occurring among horses the subcutaneous injection of an extract prepared from pure cultures of the bacillus of glanders has been employed. This so-called "mallem" causes a rapid rise of temperature to the extent of two or three degrees in glandered horses, whilst the effect upon the temperature of a healthy animal is insignificant.

Pathology.—The *post-mortem* appearances are much the same as those observed in the horse. There are the usual signs of grave blood-poisoning—early decomposition, excessive blood-staining of the vessels and tissues, and subserous petechiæ. Scattered points of suppuration are found throughout the body, and sometimes extensive hæmorrhage into the muscles. The lungs are usually more or less consolidated from pneumonia, and contain yellow nodules, softening in the centre, like the so-called pyæmic abscesses.

The microscopic characters of the lesions are the same, whether they occur in the skin or the respiratory tract. A small nodule of granulation-tissue forms and increases in size. The central part soon undergoes fatty degeneration and softening, and an ulcer is formed by the giving way of the skin or mucous membrane over it.

In 1882 Schütz and Löffler, two of the assistants in Koch's laboratory in Berlin, discovered the presence of a bacillus of a definite form in all the parts affected with the specific processes of glanders. This bacillus was cultivated for four generations out of the body in the serum of horse's blood, and finally inoculated on two healthy horses. Both animals speedily died with all the symptoms of glanders. The bacillus is very small, about the size of that of tubercle. Further observations have conclusively proved that the bacillus mallem is the actual virus of the disease, as the bacillus anthracis is of anthrax.

Duration.—The disease proves fatal usually in a week or fortnight, but may extend to a month. It occasionally assumes a chronic form in the human subject and lasts for several months.

Prognosis.—If the disease assumes the acute form, death is almost certain to follow. When it becomes more chronic, according to Durham, about one half of the cases recover.

Treatment.—Beyond the general treatment of supporting the patient, opening the abscesses, and freely using antiseptics both for the nose and the local sores elsewhere little can be done. Those who have care of the case must protect their hands by india-rubber gloves, if possible, while dressing the sores; and all dressings or rags which have become soiled with the discharges must be immediately burned.

WOUNDS WITH INOCULATION OF DECOMPOSING ANIMAL MATTER,* AND THE PRODUCTS OF UNHEALTHY INFLAMMATIONS.

Although every student of anatomy frequently cuts himself in dissecting, we rarely see any ill effects from these injuries. In some cases, however, the most serious results, terminating in permanently impaired health, or even in death, ensue. The result depends quite as much on the state of health of the person injured, as on the condition of the body from which the poison is received. If the health be broken by any cause, whether dissipation or overwork, very serious effects may follow, which would not occur if the patient had the resisting power of a sound constitution. Many persons are peculiarly liable to be affected by exposure to septic influences. They suffer in various ways,—such as nervous depression, sore throat, or diarrhoea—from working in dissecting or *post-mortem* rooms. The same thing happens from exposure to the contaminated atmosphere of a crowded hospital ward, and more especially to the exhalations arising from patients affected with phlegmonous erysipelas, pyæmia, gangrene, or other septic diseases. The susceptibility is greatest in those least frequently exposed to such infections. Those who habitually work in such an atmosphere seem to become acclimatised to it after a time. If for a time the habit is broken, they suffer on resuming their work as much as those exposed for the first time. A person so suffering in health is peculiarly liable to local or general infection on the receipt of a dissection-wound.

Causes.—The deleterious influence exercised by the dead body may be attributed to three different causes: 1, the ordinary Irritation of the Wound; 2, Inoculation of Putrid Matter; or, 3, Introduction of a Specific Septic Virus into the system. I think it probable that each of these causes may exercise a distinct influence; but the worst effects of dissection-wounds are dependent on the inoculation of a specific virus.

1. That ill effects sometimes result from the simple **Irritation of the Puncture**, is evident from the fact that mere scratches or punctures with splinters of wood, or other substances free from an actual poison, give rise to considerable local disturbance in certain states of the constitution; so, also, from operation- and dissection-wounds which are ragged and torn, such as are made by specula of bone or the teeth of a saw, are peculiarly troublesome.

2. **Putrid Animal Matter** is always irritating, but, as has before been pointed out, putrefaction cannot attack living tissues, and the effect produced is consequently limited to the local irritation caused by the chemical products of the process. A small puncture, which, if made with a clean knife, would heal by the first intention, may, if exposed to the irritation of putrid animal matter, inflame and suppurate, forming a small ulcer; but, unless the general health be seriously impaired, no further trouble is likely to occur.

3. The worst forms of *post-mortem* wounds arise from the inoculation of the **Specific Virus** of some infective inflammation, such as erysipelas, pyæmia, and septicæmia. The virus is contained in the exudation fluids from the unhealthy inflammation, and its nature has already been alluded to when discussing the causes of inflammation. In cases attended with the milder forms of localised suppuration, the virus is most commonly one of the varieties of the *staphylococcus pyogenes*. In the more severe spreading forms the *streptococcus pyogenes* is almost invariably found. The diminution of the intensity of the poison when putrefaction sets in is supposed to be due to altered conditions after death, which are more favourable to the development of the ordinary bacteria of putrefaction and less favourable to the growth of the specific organisms which consequently perish. However it is to be explained, the fact is undoubted that a few hours after death, whilst apparently quite fresh, the body is in the highest degree infective and dangerous: advanced putrefaction lessens the danger. Of all *post-mortem* poisons, that which is present in the fluid filling the cavity of the abdomen in septic peritonitis, whether following parturition or operations, is by far the most noxious. I believe it to be impossible to immerse the hand in it with impunity if there should happen to be a scratch, puncture, or abraded surface of any kind on it. Inoculation most commonly occurs through an accidental wound or scratch during the *post-mortem* examination; but a raw surface partly healed, or the fissures in chapped hands, or the small cracks so common at the margin of the nail, may equally serve as points of inoculation. In rare cases, infection takes place through the unbroken skin, the hair follicles seeming to serve as points of entrance. In the graphic account given by Sir James Paget of his own case, the poison is stated to have been absorbed through the unbroken cuticle of the hand immersed in pyæmic effusion into the pleura.

That the poisonous influence from the bodies of persons who have died of septic diseases is transmissible to others by contact or infection, cannot be denied; and accoucheurs and operating Surgeons should abstain as carefully as possible from performing *post-mortem* examinations on patients dying of such diseases, lest the poison be carried to and excite similar morbid processes in their patients. Much of the septic disease that used formerly to prevail in hospitals was engendered in this way, and infective disease has often thus been carried out of hospitals and communicated to private patients by Surgeons neglecting hygienic precautions.

Symptoms.—From what has been stated above, it would appear that there are two distinct kinds of mischief resulting from dissection wounds. First, the purely local form, proceeding from the irritation of putrid matter acting on the unbroken skin, or on a scratch or wound; and, secondly, the *trans* infective form, spreading widely from the point of inoculation.

Of the purely local affections, the most common is the small *pustule* *serotina* met with in the dissecting-room. About twelve to twenty-four hours after

inoculation the punctured part becomes painful, hot, and throbbing ; at the end of about forty-eight hours a small drop of pus is seen raising the cuticle. If this be punctured, a small superficial sore is seen beneath, and the pain is at once relieved. If the sore be now properly dressed it heals without trouble, but if not, a small scab forms, the pus accumulates beneath it, the pain and throbbing return, and are again relieved by removing the scab. This may be repeated several times. There is neither glandular swelling nor constitutional disturbance.

Suppuration in the hair-follicles and the formation of boils is an occasional result of the action of putrid fluids on the unbroken skin of the hands.

Suppuration of the matrix of the nail arises from inoculation of a fissure at the side of the nail. The root of the nail is softened and loosened by the suppuration beneath it. The condition is often very chronic, and the nail usually separates when recovery takes place.

A somewhat rare affection resulting from the frequent and prolonged contact with putrid matter is the so-called *dissecting-porter's wart* or *anatomical tubercle*. It is always seated on the knuckles or back of the hand. It consists of a warty thickening of the skin without ulceration. The surface may be moist, and the discharge if allowed to dry may form crusts ; in other cases it may be scaly on the surface. The enlarged papillæ are closely set, and the diseased condition tends slowly to spread. In the case of one of the dissecting-porters at University College who suffered from this affection, the patch measured about one inch and a half in diameter. It was cauterised without much effect, and was finally cured after many months' treatment by keeping it constantly moist, so as to prevent the formation of crusts on the surface, and by the prolonged application of equal parts of extract of belladonna and glycerine. The investigations of Riehl and Paltauf and others tend to show that, in some cases at least, this affection is tuberculous in nature.

The infective processes that arise from dissection-wounds assume two forms.

In the *milder form* the punctured part becomes painful, hot, and throbbing, in from twelve to twenty-four hours after the injury ; the finger becomes red and swollen, the lymphatics of the arm are perhaps affected, and the glands in the axilla become enlarged. There is general febrile disturbance, ushered in by agors, a feeling of depression, and often intense headache ; suppuration takes place about the puncture, and also, perhaps, in the inflamed glands, the case presenting the ordinary characters of whitlow with inflammation of the lymphatic vessels and glands.

In the *more severe form* of dissection-wound, the patient is seized, about twelve or eighteen hours after the puncture, with rigors and depression of the nervous system ; the countenance becomes anxious, the pulse quick, and there is high fever. On examining the finger, a pustule, or vesicle, with an inflamed areola, may be observed in the situation of the puncture ; from this a few red lines may be seen extending up towards the arm-pit, where there may be swelling and tension. In the worst cases, however, the signs at the seat of inoculation may be either wanting or scarcely recognizable. Suppuration, accompanied by much pain, takes place in the pectoral and axillary regions ; it is usually diffuse, the pus being mixed with shreds and sloughs. The general symptoms gradually assume an æsthenic type ; the tongue becomes brown, sordes accumulate about the lips and gums, low delirium sets in with a rapid feeble pulse, and death

occurs in from ten days to three weeks. When incisions are made into the brawny tissue, it is found to be infiltrated with thin pus, and in a sloughy state. If the patient live, large circumscribed abscesses form under the pectoral muscles, in the axilla, and above the clavicle, accompanied by much exhaustion and depression of the system. The convalescence is tedious and prolonged, and the constitution is often shattered for life.

In other cases a diffuse inflammation, identical in all its characters with the so-called phlegmonous or cellular erysipelas, spreads directly from the seat of inoculation. That this form of dissection-wound is of a truly specific character, is evident from the fact that patients labouring under it may communicate fatal erysipelas to their nurses and attendants: as happened in the case of the late J. P. Potter, of University College Hospital, whose early death was much to be lamented. It is this kind of dissection-wound that is especially apt to occur after infection from patients who have died of diffuse inflammation of the serous membranes.

Sometimes the intensity of the spreading inflammation is such that it terminates rapidly in gangrene of the affected part, and the disease then resembles in most of its features genuine spreading or traumatic gangrene. A case of this kind occurred in a nurse under the care of Christopher Heath in University College Hospital in 1880. It resulted from the prick of a pin received in laying out the body of a lady who had died of puerperal fever. The patient's life was saved only by amputation at the shoulder-joint on the sixth day after the accident. In this case, as is usual in this form of disease, there was no enlargement of the lymphatic glands in the axilla.

The symptoms produced by contact, independently of any wound, with the bodies of persons who have died of erysipelatous diseases or pyæmia, sometimes vary, though still referable to the introduction of a poison. Thus I have known a body to infect seriously in different ways six students who were working at it. Two had suppuration of the areolar tissue under the pectorals and in the axilla; one was seized with a kind of maniacal delirium; a fourth had typhoid fever; and the remaining two were seriously, though not dangerously, indisposed.

TREATMENT.—On the receipt of a puncture in dissection or in making a *post-mortem* examination, the best way to prevent injurious consequences is to tie a string tightly round the finger above the injury, thus causing the blood to flow, and perhaps to carry the virus out with it. The part should then be well washed in a stream of cold water at a tap, or better still in a solution of carbolic acid (1 to 20 of water), or of perchloride of mercury (1 to 500), and sucked for some minutes; in this way any poisonous matter that has been introduced may usually be got rid of. It is better not to apply nitrate of silver; it irritates the finger, and fails to penetrate to the deep part of the puncture. Dissectors should bear in mind that the state of the constitution exercises great influence upon the effects of the puncture; and that, in proportion as the health is sound and the body not exhausted by overwork, there is less likelihood of any injurious consequences ensuing.

In the slighter forms of dissection-wound, attended by a moderate amount of inflammation, the whole finger should be thickly painted with extract of belladonna diluted with an equal quantity of glycerine; this should be covered with cotton-wool, or with warm fomentations of boric acid lint, while the hand should be elevated and kept at absolute rest in a sling or in a splint. If

the lymphatics become inflamed, the belladonna and glycerine should be thickly painted along their course, and the arm enveloped in cotton-wool.

The general treatment of clearing out the bowels with a free purge, followed by moderate stimulation, must be adopted in the early stage; but tonics and strong support will soon be required, and if there be much constitutional irritation, opiates may advantageously be administered.

The treatment of the more severe forms of dissection-injury consists principally in the application of glycerine and belladonna with hot fomentations in the early stages, followed by early and very free incisions into the finger, axilla or pectoral region, or wherever else the part may become tense and brawny. These should be made, if there is much tension, even though matter have not already formed, with a view of preventing suppuration. Should abscesses form, they must be opened early. All incisions should be made with antiseptic precautions, and treated afterwards by some of the modes of antiseptic dressing already described. Even when sloughs have formed, they are not putrid, and the patient's danger will be greatly increased should they be allowed to become so. In the constitutional treatment, our great reliance, after administering a free purge, is on the administration of bark, ammonia, wine, and brandy, with such fluid nourishment as the patient can take; the case being treated as one of the worst forms of asthenic inflammation. If the patient survive, he must be sent as soon as possible into the country, and must devote some months, perhaps, to the re-establishment of his health. The punctured part often continues irritable for a great length of time, even for many years, remaining red, inflamed, and desquamating, pustules sometimes appearing on it. This condition is best remedied by the occasional application of nitrate of silver.

In conclusion, I cannot too strongly urge upon the dissecting student that, unless he take scrupulous precautions as to cleanliness and disinfection, he may readily contaminate with septic poison any patient whose wound he dresses. No dissecting student or operating Surgeon who has examined a dead body ought to approach a patient who has an open wound without changing his coat and thoroughly disinfecting his hands, by washing them for at least five minutes in hot water and soap, and afterwards soaking them in some strong antiseptic solution, such as carbolic lotion (1 in 20), solution of perchloride of mercury (1 in 1000), or tincture of iodine and water (3ij to Oj).

CHAPTER XII.

EFFECTS OF HEAT AND COLD.

BURNS AND SCALDS.

A **Burn** is the result of the application of a degree of heat sufficient to produce inflammation of the part upon which it acts, or even charring and complete disorganization of its tissues. A **Scald** is occasioned by the action of some hot fluid, giving rise to the same destructive effects, although the appearances produced are different.

LOCAL EFFECTS.—Burns and scalds vary greatly in the degree of destruction of tissue to which they give rise: this variation depending partly upon the intensity of the heat, and partly upon the duration of its application. The sudden and brief application of flame to the surface causes but very slight damage to the cuticle, with some hyperemia of the skin. If the part is exposed for a longer time to the action of the flame, as when a woman's clothes take fire, the cutis itself may be destroyed; and if the heat be still more intense, as when molten metal falls upon the body, the soft parts may be deeply charred, or the whole thickness of a limb destroyed. So, also, the effects of scalds vary greatly, not only according to the temperature of the liquid, but according to its character; the more oleaginous and thick the fluid, the more severe, usually, will the scald be.

These various effects of heat have been arranged by Dupuytren into six degrees. This is a classification of great practical importance, as the degree and character of the resulting cicatrix are dependent on the depth to which the burn penetrates.

In the *first degree*, the application of heat has been momentary. It is followed by redness and pain. There is dilatation of the vessels, simple hyperemia, but no destruction of tissue: and consequently there is no resulting cicatrix. The constant repetition of a burn of this degree may, however, cause a disturbance of healthy nutrition. Thus in old people who sit constantly before the fire or over charcoal foot-warmers, the skin of the legs, especially in front, becomes pigmented and indurated, as a consequence of the frequently recurring hyperemia induced by the heat. Ulceration readily occurs from slight causes in the damaged integument.

In the *second degree* the injury done by the heat is sufficient to cause dilatation of the vessels, retarded blood-flow, and exudation. The corneous layer of the cuticle is loosened and raised from the Malpighian layer by the exudation from the vessels of the inflamed cutis, and thus vesicles or blisters are formed. When these burst, the surface left beneath is still completely covered with epithelium. There is no loss of substance beyond that of the corneous layer of the cuticle. The raw surface left may discharge a little puriform fluid, the cells which it contains being partly young epithelium from the Malpighian layer and partly leucocytes which have wandered to the surface. Although

no cicatrix results in these cases, yet discoloration of the integument is often left. If the cuticle be not removed, the inflammation speedily subsides and is followed by desquamation.

In the *third degree* the whole of the cuticle is destroyed, with a portion of the true skin, but the *cutis vera* is not entirely destroyed. This is a most important point, as it materially influences the character of the resulting cicatrix. The thin layer of the true skin remaining contains sweat-glands, hair-follicles and elastic tissue—structures which are not reproduced if once destroyed. Moreover, round each hair, in the ducts of the sweat-glands and in the hollows between the papillæ, epithelium is left uninjured, from which new cells can start growing. The tips of the papillæ have their epithelium completely destroyed, and consequently become covered with granulation-tissue, so that the whole surface assumes a vivid red tint and suppurates freely. It is, however, covered with epithelium with marvellous rapidity, owing to the innumerable points from which the new cells start growing. It scarcely contracts in healing, and the scar that results is elastic and contains all the elements of normal skin. Owing to the exposure of the nerve-endings in the papillæ this form of burn is intensely painful.

In the *fourth degree* there is destruction of the skin through its whole thickness, so that the subcutaneous tissue is reached. The eschar separates by ulceration from the surrounding parts, and a large granulating sore is left which can become covered by epithelium only from its edges. Consequently the healing is slow and attended with long-continued suppuration and great contraction. The resulting cicatrix is, therefore, much smaller than the original raw surface, and is devoid of glands, hair, and elastic tissue; at first it is thin, red, or purplish, glazed, often in the form of bands or bridges, and is apt to occasion great deformity by the cohesion of parts, as of the fingers or by contraction, as at the elbow, and the side of the neck and face, or by the closure of apertures, as of the nostrils.

Most severe burns reach the fourth degree in some part at least of their extent. In practice it is not easy to distinguish between the third and fourth degrees until the sloughs begin to separate, but when the skin is hard and parchment-like and brownish-yellow in colour, the burn has probably reached the higher degree.

In the *fifth and sixth degrees* the destructive influence of the burn penetrates to a greater or less depth into the muscles, bones, or joints. In the fifth degree, the more superficial muscular structures are implicated; in the sixth degree the whole thickness of the limb is destroyed and charred.

These various degrees are usually found associated to a greater or less extent; indeed, in the more severe cases, the first three or four degrees are almost invariably met with together.

The scars of burns have been credited with some peculiar power of contraction, but there is no reason to believe that the granulation-tissue formed to repair a loss of tissue presents any differences corresponding to the particular injury which caused the mischief. Burns are the injuries in which the largest granulating sores are met with; and, as we have before seen, contraction is an essential part of healing, and the amount is directly proportional to the size of the sore and the looseness of the parts. This process of contraction continues for many months after the sore has become covered with epithelium, giving rise frequently to the most distressing deformities, sometimes rendering a limb

completely useless. These cicatrices are composed of dense fibrous tissue, and often extend deeply between and bind together the muscles, vessels, and soft structures of a limb, of the face, or of the neck.

CONSTITUTIONAL EFFECTS.—When in an ordinary conflagration a person is "burnt to death," the fatal event is occasioned not by the charring of the body, but by asphyxia. Life is mercifully extinguished by suffocation in the smoke before the body itself is consumed. To what particular product of combustion the asphyxia is due, is somewhat uncertain. There is reason to believe that in most cases carbon monoxide rather than carbon dioxide is the cause of suffocation. If the patient is not killed outright, the constitutional effects resulting from burns are most serious and important; they depend not so much upon the depth of the injury as upon its situation, the extent of surface implicated, and the age of the patient. Thus a person may have his foot completely charred by molten iron, with far less constitutional disturbance and danger than if a larger surface of the body be scorched to the first and second degrees. Burns about the chest, the head, and the face, are thought to be more likely to be attended by serious constitutional mischief than similar injuries of the extremities. Children generally suffer more severely from burns than adults. The fever that follows a bad burn is partly due to the reaction after extreme depression, but the two chief causes are undoubtedly the inflammation produced by the burn and the absorption of the products of putrefaction from the raw surface. Experiment has shown that the charred surface resulting from a burn, so far from presenting a barrier to the entrance of septic matter into the system, as is sometimes supposed, is in reality equal in its power of absorption to a raw surface made with a knife. Unless special precautions are taken, therefore, to prevent decomposition in the sloughs, the amount of septic products absorbed is very large, and the resulting fever proportionally severe.

After a severe burn the constitutional disturbance may often be divided into three stages: 1, Depression and Congestion; 2, Reaction and Inflammation; 3, Suppuration and Exhaustion.

1. The stage of **Depression of the Nervous System and Congestion of Internal Organs**, occupies the first forty-eight hours; during which death may occur. Immediately on the receipt of a severe burn the patient becomes cold and collapsed, and is seized with fits of shivering, which continue for some time. He is suffering evidently from *shock*, and the severity of the shivering is usually indicative of the extent of the constitutional disturbance. It is more prolonged in those injuries that occupy a great extent of surface, even though the burn be only of the first or second degree, than in those which, being of more limited superficial extent, affect the tissues deeply. In many cases of extensive burn the patient suffers no pain although perfectly conscious. This is a very grave sign, indicating the severest shock. On the subsidence of the symptoms of depression, there is usually a period of quiescence before reaction comes on. At this time *vomiting* is a common and troublesome symptom, and the patient, especially if a child, not unfrequently dies comatose; death resulting from congestion of the brain and its membrane, with, perhaps, serous effusion into the ventricles or in the subarachnoid space. Besides these lesions, the mucous membrane of the stomach and intestines, as well as the substance of the lungs, may be found congested.

In 40 *post-mortem* examinations made at University College Hospital in

cases of burn proving fatal within forty-eight hours, the contents of the cranium are stated to have been congested in 15, several of which showed excess of fluid in the subarachnoid space and in the ventricles; in 18 there was congestion of the lungs; and in 17 the abdominal viscera were more or less markedly congested, the kidneys alone being affected in 2, and the duodenum in 2; in one case there were "two or three small ulcers" in the third part of the duodenum.

2. The next stage, that of **Reaction and Inflammation**, extends from the second day to the second week. The action of the heat which causes the burn is momentary, and produces its full effect instantaneously. The inflammation which is the direct result of the heat sets in therefore at once, and if no other cause came into play it would be accurately limited to the part acted on, and begin to subside after the first few hours. This is, however, not the case in the majority of burns. By the end of the second day the inflammation is still increasing in intensity and extent. The burnt area is surrounded by a wide-spreading blush of redness; swelling, heat, and pain become prominent symptoms. With these there is fever proportional to the extent of the burn. It is important to consider, therefore, what is the cause that not only maintains but extends the inflammatory process long after the original cause has ceased to exert any influence. In burns accompanied by death of considerable portions of tissue, the presence of the dead matter no doubt gives rise to some irritation in its immediate neighbourhood, but the great cause of the inflammation that occurs during the first week of a bad burn is the decomposition of the adherent sloughs, and the fever that accompanies the process is in great part due to the absorption of the chemical products of putrefaction. It is during this period that a large burn becomes so horribly offensive unless special means are adopted to prevent it. Death during this stage may be connected with some inflammatory condition of the gastro-intestinal mucous membrane or of the peritoneum. The lungs are also frequently affected, showing marked evidence of pneumonia or congestion; cerebral affections are less common than in the first stage, though they may present more unequivocal evidence of inflammation.

In 38 cases examined *post-mortem* during this stage, the brain and its membranes were congested in 7; the lungs were congested in 15; there was pneumonia in 2, bronchitis in 4, and petechiæ in 3; the abdominal viscera showed a generally congested state in 5, whilst in 5 the stomach and duodenum only were affected, the duodenum alone in 4, and the kidneys alone in 1. In one case there were two ulcers in the first part of the duodenum. The *post-mortem* appearances are, in fact, those of acute septic poisoning, possibly complicated in some cases by a true infective process.

It is in this stage of burn that the very serious and rare sequela, **perforating Ulcer of the Duodenum**, may occur. Attention was first directed to it by Curling, who suggested that the ulceration commenced in Brunner's glands. It is far more probable that it is due to the acid contents of the intestine acting on a point in the mucous membrane in which a capillary embolism has lodged. In favour of this view are the following facts: first, the ulcer occurs most frequently at that period of the case in which the patient is suffering from the absorption of septic matter from the sloughs in the skin, a condition in which capillary embolism is of common occurrence; secondly, it is usually met with in the first part of the duodenum near the pylorus before

the contents of the bowel have been neutralised by the bile; thirdly, signs of active inflammation are usually wanting in the mucous membrane surrounding the ulcer; and lastly, a similar ulceration has been recorded as occurring in a case of septicæmia not due to burn. The ulcer may rapidly proceed to perforation, exposing the pancreas and possibly eroding the superior pancreaticoduodenal artery and causing fatal hæmorrhage. In other cases it may open into the serous cavity of the abdomen and cause death from peritonitis. Ulceration of the duodenum is met with most frequently in patients under ten years of age, but as extensive burns are most common in children, it may not be proportionally more frequent in them than in adults. It is said rarely to occur before the tenth day, but Caesar Hawkins met with it once in a child six years old, who died four and a half days after the burn; and in a child nine years of age, who died on the fourth day, in University College Hospital, I found an ulcer in the duodenum about the size of a shilling, with sharp-cut margins. In this case the mucous membrane generally was inflamed. That these ulcers are not invariably fatal is evident from a case mentioned by Curling, in which, on death occurring from other causes, eight weeks after the injury, a recent cicatrix was found in the duodenum. Ulcer of the duodenum seldom occasions any very marked symptoms to indicate the nature of the mischief; the patient generally sinks suddenly. In some instances there is hæmorrhage, though this is not an unequivocal sign, as I have several times seen bleeding from simple inflammatory congestion of the intestinal mucous membrane. Pain in the right hypochondriac region, and perhaps vomiting, may also occur.

In 94 consecutive examinations after death from burns, ulceration of the duodenum was found in only two cases.

3. The stage of **Suppuration and Exhaustion** continues from the second week to the close of the case. In it we frequently have symptoms of hæmoptoe, with much constitutional disturbance from the long continuance of exhausting discharges. If death occur, it is most frequently induced by inflammation of the lungs or pleura; affections of the abdominal organs and brain being less frequent during this stage of the injury. Pyæmia is not uncommon.

In 16 cases ending fatally after the second week, congestion of the brain was found in 2; in 6 cases there was pneumonia, and in 3 bronchitis; the abdominal viscera were free from congestion in 13, whilst in 2 there was congestion of the stomach and intestines, and in 1 of the duodenum only. In no case was the duodenum ulcerated.

PROGNOSIS.—The influence of extent, degree, and situation on the prognosis of burns, has already been stated. The most fatal element in these injuries is *superficial extent*. It is generally believed that recovery cannot take place if one-third of the surface of the body be affected. Not only are the cutaneous nerves greatly irritated, and the nervous system generally severely affected from the shock of an extensive burn; but, owing to the arrest of the cutaneous secretion over a large surface of the skin, congestion of the internal organs and of the mucous membranes ensues: hence death may happen directly from this cause, or from the supervention of inflammation in the already congested parts, more particularly in the early periods of life. The *degree* of burn influences the prognosis unfavourably rather as far as the part itself is concerned, than as the general system is affected. The most fatal *period* in cases of burn is the first week after the accident. In 100 cases of death from

these accidents, 73 proved fatal before the eighth day ; 42 of these dying on the first day. Of the remaining 27 cases, 12 died in the second week, 9 in the third, 3 in the fourth, 2 in the sixth, and 1 in the ninth.

TREATMENT.—The treatment of burns must have reference to the constitutional condition, as well as to the local injury. A vast variety of local applications have been recommended by different Surgeons, such as flour, starch, cotton-wadding, treacle, white paint, gum, solution of india-rubber, &c. ; the principle of all these applications is, however, the same, viz., the protection of the burnt surface from the air. I shall here content myself with describing the methods that are usually followed with much success at the University College Hospital.

The **Constitutional Treatment** is of the utmost consequence. We have seen how death occurs at various periods after these accidents from different causes, and we must modify our treatment accordingly. The first thing to be done after the infliction of a severe burn is to bring about reaction ; the patient is trembling, in a state of extreme depression, suffering great pain, and cold and shivering, and he may sink from the shock unless properly supported. Under such circumstances the local treatment of the burn must be postponed until the shock has been relieved. A full dose of liquor opii, varied according to the age, should be given at once in some warm brandy-and-water, and repeated, if necessary, in the course of an hour or two ; and the patient should be wrapped in hot blankets.

When the body is extensively but superficially burnt, the immersion of the patient in a warm bath gives instantaneous relief, soothing the pain and removing the depression.

When reaction has fairly set in, the patient's secretions should be kept free by the administration of an occasional mild purgative. Should any inflammatory symptoms about the head, chest, or abdomen manifest themselves, appropriate treatment is required. I have certainly seen patients saved in these circumstances by blood-letting and the application of leeches. But, in the vast majority of instances, the visceral complications are of a congestive type. In such cases our great reliance must be on stimulants. Anomonia and bark, brandy and wine, require to be given freely, with a sufficiency of nourishment ; and the irritability of the nervous system must be soothed by frequent and full doses of opium. At a later period, when the strength has become impaired by the profuse discharges, this tonic and stimulating plan must be actively continued.

Local Treatment.—In all cases of extensive burn the charred clothes must be removed, and the patient laid upon a blanket and protected as far as possible from exposure to cold. The objects aimed at in the further treatment are the protection of the raw surface, which in all degrees of burn below the fourth is acutely sensitive, the prevention of decomposition, and the exclusion of cold. In burns of the first degree no treatment is necessary beyond protecting the surface from the air. In cases where scorching of the face results from a gas explosion, Heath recommends that the skin be painted with a mixture of one part of collodion and two of castor-oil. In burns of the second degree the blisters may be punctured and the fluid allowed to drain away, but the cuticle should not be removed. The whole part may then be wrapped in cotton-wool and left untouched for a few days, by which time it will have quite recovered. In the third and succeeding degrees of burn, sloughs

have to separate and suppuration will take place, and prevention of decomposition consequently becomes of the first importance. The extent of the raw surface, however, and the readiness with which absorption takes place from it, render it unsafe to apply any antiseptic possessing powerful toxic properties, and for this reason it is better not to use carbolic acid or perchloride of mercury. Boric acid, salicylic acid, eucalyptus oil, and creolin, are the most powerful of the non-toxic antiseptics. Boric acid may be applied either by means of boric lint soaked in a concentrated solution of the acid and covered with oiled silk, or as ointment (p. 212) spread on strips of linen. If much sloughing is expected, the former is the better plan; if little, the latter. The dressing must be changed every day after suppuration has commenced. This is usually a very painful process, as even the ointment adheres more or less to the raw surface. To overcome this difficulty and at the same time to cleanse the parts thoroughly, warm boric acid baths are of the greatest service. The patient should be immersed in the bath with the dressing on, and the latter should be carefully removed when it is thoroughly soaked. The bath should be as warm as the patient can comfortably bear, and he should remain in it for about half an hour. About ten drachms of boric acid to every gallon of water makes an efficient antiseptic bath. If there is much discharge it should be absorbed by a layer of salicylic wool over the boric dressing in order to prevent putrefaction as far as possible. Creolin has been used with the best results; it may be employed as a lotion or ointment, in the strength of $\frac{1}{2}$ to 2 per cent. Iodoform may be sprinkled on the surface if the discharge becomes foul, but caution must be used in its application, especially in children, as symptoms of poisoning (p. 212) may arise. In the absence of the necessary materials for these modes of treatment the following plan will be found comfortable to the patient, and satisfactory in its results. The whole burnt surface, whatever may be the degree of burn, should be well covered with the finest wheaten flour by means of an ordinary dredger. The flour should be laid on thickly, but uniformly and gradually; it forms a soft and soothing application to the surface. If the cuticle have been abraded, the flour will form a thick crust, by admixture with the serum discharged from the broken surface. If the skin be charred, the discharge which will speedily set up around the eschar will make the flour adhere to the part, forming, as it were, a coating impervious to the air. The crusts thus formed should not be disturbed until they become loosened by the discharges, when they should be removed. In this mode of treatment the decomposition of the discharges is retarded and limited by the dryness of the dressing.

A common remedy in iron-works and other places where burns are common is the so-called *Carron-oil*, composed of equal parts of linseed-oil and lime-water, to which a small quantity of spirits of turpentine is sometimes added. It is applied on lint. Whatever local application be adopted, I hold it to be of the utmost importance in the early stages of the burn to change the dressings as seldom as possible; if dry dressings are used, they should not be changed until they have been loosened by the discharges. Every fresh dressing causes the patient very severe pain, produces depression, and materially retards the progress of the case.

When the sloughs have separated, the granulating surface must be managed on ordinary principles. It is important, however, to select some form of

dressing that will not stick to the sore, otherwise the granulations may bleed every time it is changed to such an extent as seriously to weaken the patient. To prevent this, the green "protective" oiled silk may be applied directly to the sore and covered with dry boric lint or salicylic wool; under this plan of treatment the dressing is perfectly painless. If the granulations become prominent they must be touched with nitrate of silver. Epithelium-grafting is often very useful in hastening the healing.

Prevention and Removal of Contraction.—The most serious deformity may result from the contraction which necessarily occurs during the cicatriza-

Fig. 114.—Cicatrix of Lip and Neck.

Fig. 115.—Contraction of Elbow from Cicatrix of Burn of Fourth Degree.

tion of a large granulating surface. After burns about the chin and front of the neck the lower lip becomes everted, and the chin drawn down towards the sternum (Fig. 114); and in burns on the inside of limbs or at the flexures

Fig. 116.—Dislocation backwards of little finger from contraction of the cicatrix of a Burn of the Fourth Degree.

Fig. 117.—Deformity of Left Hand from Burn of the Fifth Degree.

of joints, more especially the elbow, the contraction may greatly impair the utility of the part (Fig. 115). In bad burns of the hands the fingers may be drawn into the palm, may become webbed together, or may be dislocated and fixed immovably against the dorsum (Figs. 116 and 117).

Similar contractions may occur in the foot, leaving great deformity, as in Fig. 118, where the heel is shown to be retracted, and the whole of the toes spread out in a fan-shape. In this case Pirogoff's amputation was the only means left of securing an useful limb.

Corrosive fluids, such as strong sulphuric acid, produce effects very similar to those that result from the more severe degrees of burn; the cicatrices are irregular and contracted, and often rugged and warty.

In the treatment of the granulating surface left by a burn, much may be done to limit the amount of contraction by employing the method of skin-grafting recommended by Thiersch. This has already been described on page 278; it is a most valuable method of treatment, and is especially applicable to burns about the face in which deformity of the lips or eye-lids is likely to follow. During the healing process the part must always be fixed in a proper position by means of bandages, splints, and mechanical contrivances adapted to counteract the tendency to contraction of the cicatrix, and the consequent deformity.

Fig. 118. — Deformed Foot from Burn of the Fourth and Fifth Degrees.

The contracted cicatrices resulting from burns may, if of recent date, be stretched out by the pressure of strips of plaster or elastic bandages, the traction of india-rubber bands, or the action of rack-and-pinion apparatus. The good effect of this plan of treatment is especially marked in contractions at the elbow, or in those that fix the arm to the side. These means are particularly

useful in children, and indeed are so in all cases, provided the cicatrix be not too old—not more than a year; after that time, it will seldom yield without division.

Operations for the Removal of the Effects of Contraction consequent upon burns are occasionally required, and may do much to improve the patient's condition. The operations are of two kinds: 1. Simple division of the Faulty and Contracted Cicatrix; 2. The Transplantation of a flap of adjacent healthy Skin into the gap left after the division of the cicatrix.

1. In the first operation, that of simply **Dividing the Cicatrix**, three points require special attention: 1st, that the division extend completely through the cicatrix from side to side into the adjacent healthy skin; 2ndly, that the incision be carried through the whole depth and thickness of the cicatrix into the healthy adipose tissue beneath it, which may always be recognised by its yellow colour; 3rdly, that all contracted bands lying in this layer be fairly divided. The great obstacle to the success of this operation, however, consists in the fact that the new granulations, which spring up after the division of the contracted cicatrix, in their turn contract whilst healing. After the division of the cicatrix, also, it may be found that the subjacent structures have been so rigidly fixed in their abnormal position as not to admit of extension. It may then be necessary to employ screw-apparatus, or even to divide fasciæ and tendons, before the part can be restored to its normal shape. Care must, however, be taken in doing this, that subjacent structures of importance, such as large blood-vessels, or nerves, be not so closely connected with the cicatrix as to render wound or division of them unavoidable. In the neck, cicatricial bands will often come into very dangerous proximity

to the external jugular vein, which becomes greatly distended by the pressure thus exercised upon it. And at the elbow, which is a common seat of contraction from burns, the brachial artery may become involved in the cicatrix to a dangerous extent. I have heard of one case in which this vessel was divided in cutting through the cicatrix, when amputation of the arm was immediately resorted to.

These operations are most successful in cases of contraction at the flexures of the joints. If the contraction be of very long standing, the arteries and nerves will have become shortened, and incapable of stretching under any force that may safely be employed; hence they may easily be torn.

2. Operations undertaken for the removal of the disfigurements that occur about the face and neck as the result of burns, require much management. In these cases, simple division of the cicatrix is insufficient; and **Transplantation of a Flap of Skin** is required in addition. After the cicatrix and all cicatricial bands have been freely divided in accordance with the rules just given, a flap of integument, of sufficient size to fill the greater part of the gap, must be dissected up from the neighbouring parts of the neck, chest, or shoulder, and laid into the cicatrix. There it should be fixed by sutures; but extreme care must be taken that no traction be put upon it, lest

Fig. 119.—Incisions in Teale's operation for Cicatricial deformity of the Lower Lip.

Fig. 120.—Teale's Operation: the Flaps in place.

it slough. Even if union takes place by the second intention a very satisfactory result may often be obtained.

The flaps must be cut much larger than the raw surface which they are intended to fill, in order to allow for the shrinkage due to the elasticity of the skin. Croft has obtained excellent results by operating in two stages. First, a strip of skin is raised from the healthy surface near the cicatrix, but is left attached at its two ends until the under surface has granulated. During this time the skin is prevented from re-uniting by a strip of protective oiled silk slipped beneath it. Secondly, the cicatricial bands are freely divided, and after cutting through one end of the bridge of skin, the latter is drawn across the raw surface and adjusted with sutures. In one case treated by Croft in this way, the strip of skin measured nine inches in length and two and a half inches in breadth. The directions given by Teale for the restoration of the lower lip when dragged down, everted, and partially destroyed by cicatrization following a burn, are so simple and lead to such excellent results, that I give them nearly in his own words. The everted lip is divided into three parts, by two vertical incisions three-quarters of an inch long, carried down to the bone. These incisions are so planned that the middle portion between them (Fig. 119, B) occupies one-half of the lip. From the lower end of each incision the knife is carried upwards to a point one inch beyond the angle of

the mouth (A). The two flaps thus marked out are freely and deeply dissected up. The alveolar border of the middle portion is then freshened. The lateral flaps (Fig. 120, C A) are now raised, united by sutures in the mesial line, and supported as on a base by the middle flap, to which they are also attached by a few points of suture, leaving a triangular even surface (C C) to granulate. In addition to the division of the cicatrix, James, of Exeter, in these cases very successfully employed a screw-collar, by which the chin can be loosened from the sternum, and gradual extension of the cicatrix effected.

In some cases of burns of the arm in which the sore will not heal, or in which the tense scar renders the limb useless, improvement may be obtained by shortening the limb. Thus, Syme in one case excised the elbow for a burn of the back of the arm which could not be got to heal, and in this way a very useful though shortened limb remained. A portion of the humerus may be removed in the same way, and the ends of the fragments wired together.

Warty Cicatrices.—The cicatrices of burns, especially on the neck and chest, occasionally become after a time projecting, red, and glazed, as if composed of a mass of fungating granulations, smoothed down and thinly skinned over. This condition resembles keloid in appearance, and has been met with chiefly in children; but I have several times seen it in adults, especially in women who had been badly burnt by their dresses taking fire. In these cases I observed, what I have noted in other similar instances in children, that the warty cicatrices were the seat of the most intolerable itching, which no external application seemed to relieve. I have, however, seen the pruritus mitigated by the administration of large doses of liquor potassæ. If small and narrow, these cicatrices may be dissected out; if large, they cannot be removed without risk of much hæmorrhage, for, although fibroid, they are very vascular.

The scars of burns or scalds form the most common seat of this "false" keloid. The cause of this peculiar outgrowth is altogether unknown. It may in some cases, perhaps, be owing to want of care in checking the luxuriance of the granulations; but in other cases it occurs though every attention is paid to the healing of the wound.

The cicatrix of a burn may become the seat of a malignant growth many years afterwards. I have removed a large epithelioma from the cicatrix of a burn, on the forearm of a woman, seventy years after the infliction of the injury, which happened when she was three or four years of age.

Primary Amputation may be required if the burn have destroyed the whole thickness of a limb; the part should then be removed at once, at the most convenient point above the seat of injury. This operation may be required also at a later period, if, on the separation of the eschars, it be found that a large joint has been opened, and is suppurating; or if the disorganization of the limb be so great as to exhaust the powers of the patient in the efforts at repair. Great caution, however, should be employed in determining on the propriety of primary amputation when the burn has extended, though in a minor degree, to other parts of the body, lest the powers of the patient be insufficient for the double call that will thus be made upon them.

Electric Stroke.—Death from lightning stroke is not a very unfrequent occurrence, and since the introduction of electric lighting several deaths have occurred from accidental contact with wires through which a powerful current

is passing, or with electro-motors. The constitutional symptoms produced are those of shock, which may prove instantly fatal, without any signs of external injury. In other cases, even though the shock has been severe, recovery has followed the employment of artificial respiration and the administration of stimulants. Extensive burns of the clothes and the surface of the body may be produced by lightning; the skin is scorched in broad bands or in narrow lines arranged in an arborescent manner. Fractures of the bones have rarely been recorded. In cases followed by recovery severe pains in the limbs may persist for several days after the injury; and, in several cases recently described in detail by Surg.-Capt. Trask, two still complained of a sense of weakness in the limbs nearly three months afterwards.

The *post-mortem* appearances after death from lightning stroke are not characteristic. *Rigor mortis* is usually well marked; the blood may coagulate imperfectly. The surface of the brain and its membranes are often congested.

FROST-BITE.

When the body has been exposed to severe or long-continued cold, we find, as in the case of burns, that local and constitutional effects are produced.

LOCAL INFLUENCE OF COLD.—This is manifested chiefly on the extremities of the body, as the nose, ears, chin, hands, and feet, where the circulation is less active than in the more central parts. It occurs to an injurious degree chiefly in very young or aged persons, or in those whose constitutions have been depressed by want of the necessaries of life. In such persons frost-bite and the resulting gangrene are as much due to the feeble vitality of the extremities as to the low temperature to which they are exposed.

The extreme parts of the body, as the feet, more especially the toes, necessarily suffer most frequently, in many cases from long exposure to wet at low temperatures rather than to dry cold. The fingers, the tip of the nose and chin, and the prominences of the cheeks, are especially apt to suffer from dry cold, more particularly when its effects are much increased by high wind; for it is a well-known fact that extremely low temperatures are borne with impunity so long as the air is calm, as, happily, it commonly is in these circumstances. But if a high wind springs up, the heat of the body is so rapidly carried off, that sudden congelation of exposed parts may ensue. It is remarkable how some parts escape. Thus the eyeball is never, to my knowledge, frozen so long as life remains, and yet it might be supposed that the aqueous humour at least would easily congeal. The eyelids, also, thin as they are, commonly escape frost-bite.

The first effect of cold is to cause a contraction of all the involuntary muscular fibres of the part acted on. The small arteries of the skin become much narrowed that the circulation through the part is completely arrested. It becomes somewhat shrunken and of a dead white colour. In this condition, being deprived of its natural source of heat, it readily becomes frozen if exposed to a sufficiently low temperature. The experience of the production of local anaesthesia by cold teaches us, however, that the tissues may be completely frozen and kept in that state for a minute or more without suffering any injury. If, however, this condition be maintained for a longer time, it is evident that the vitality of the part will be gradually lowered till finally it is completely extinguished. So long as the part is kept bloodless, inflammation

cannot manifest itself ; but as soon as the vessels dilate on the restoration of the natural heat of the part, inflammatory phenomena occur varying with the degree of impairment of vitality that the part has suffered during its exposure to cold. If it have been completely killed, the blood fails to enter the vessels of the dead part, which consequently remains white and cold till decomposition sets in. If the damage have been short of this, the blood enters the vessels, and all the phenomena of inflammation are developed. If, from the too sudden thawing of the frozen part, a large quantity of blood be admitted at a high degree of pressure, abundant exudation takes place from the damaged vessels, great swelling and tension ensue, and the circulation may again be arrested, partly by the pressure caused by the exudation, which may extinguish such remains of vitality as are left in the tissues, and partly by the obstruction to the circulation within the vessels from adhesion of the corpuscles. Thus a part which had escaped death from the direct action of the cold may rapidly become gangrenous after a short period of apparent restoration. If it escape gangrene the inflammation gradually subsides, often being accompanied by vesication. If the damage done be still less, the restoration of warmth is followed merely by some redness and possibly a little swelling with much burning pain. The effects of cold, in fact, form one of the best illustrations of the facts that inflammation is the direct result of damage of a part to a degree short of causing death, and that the degree of inflammation is proportional to the extent to which the vitality is lowered.

When gangrene results it is most commonly of the moist variety : the part is swollen and black, finally it becomes dry and shrivelled, and separates by the formation of a line of ulceration around it.

The *Constitutional Effects* of a low temperature need not detain us. It is well known that, after exposure to severe or long-continued cold, a feeling of heaviness and stupor comes on, and gradually creeps on to an overpowering tendency to sleep, which, if yielded to, terminates in coma, and a speedy, though probably painless, death.

TREATMENT OF FROST-BITE.—This consists in endeavouring to restore the vitality of the frozen parts. The great danger is that the circulation may again become arrested, as above described, by the sudden admission of a large quantity of blood at a high degree of pressure. In order to prevent this accident, the temperature must be elevated very gradually and with extreme care. The patient should be placed in a cold room, without a fire, any approach to which would certainly lead to the destruction of the frost-bitten members. These must then be gently rubbed with snow, or with cloths dipped in cold water, and held between the hands of the person manipulating : as reaction comes on, they may be enveloped in flannel or woollens, and a small quantity of some warm liquid or spirit and water may be administered. In this way sensibility and motion will be gradually restored, often with much burning and stinging pain, redness, and vesication of the part. If gangrene have come on, or if sloughing follow the restoration of the circulation, the slough, if of small size, should be allowed to detach itself by the natural process of separation, which should be interfered with as little as possible, the vitality of the parts continuing at a low ebb, and extension of gangrene being readily induced. If the gangrene be extensive, amputation may be required. This should be done at the most convenient situation, as soon as the line of separation has fully formed.

If the person who has been exposed to cold be apparently dead, he must be put in a cold room, the temperature of which must be very slowly raised. Friction, as just described, should be practised, and artificial respiration set up. These means must be continued for a long time, even if no signs of life appear; there being on record instances of recovery after several hours of suspended animation.

CHILBLAIN is a mild form of frost-bite occurring in children and in delicate adults. It occurs on the toes and fingers, and occasionally on other exposed parts, as the nose or ear. It is especially likely to occur in paralyzed or diseased limbs. Most commonly the inflammation does not extend beyond redness and swelling, with burning pain or intense itching. In more severe cases the inflammation of the skin extends to vesication, and occasionally, when the blister bursts, a small slough of the superficial part of the cutis, or in some cases even of its whole thickness, is found beneath. This forms the so-called "broken chilblain."

Treatment.—Very bad chilblains in children, or chilblains of any kind in the adult, are indications of some degree of debility. Healthy exercise, good diet, warm clothing, wash-leather socks, and tonics are useful. Locally, as a preventive, friction with spirits of wine or camphorated oil is useful: in the simple erythematous stage, the application of tincture of iodine is often recommended, or soap liniment to which a little chloroform has been added. Belladonna and soap liniment in equal parts allay the intolerable itching. If a rough forms, boric acid lint or ointment forms a useful application. Unguentum resinæ hastens the healing.

CHAPTER XIII.

INJURIES OF BLOOD-VESSELS.

INJURIES OF VEINS.

VEINS are very commonly wounded suicidally, accidentally, or in surgical operations; but, unless they are deeply seated, injuries of them are seldom attended with any serious consequences. Occasionally subcutaneous rupture or laceration of a vein takes place from a blow or strain. In such cases extensive extravasation of blood will occur, which, however, usually undergoes absorption in a few weeks; but it may suppurate, or the changes described at p. 312 may take place. This accident is most commonly seen in the internal saphenous vein.

There are three sources of danger in open wounds of veins: 1. Loss of Blood; 2. Septic or spreading inflammation of the vein; 3. Entrance of Air into the Circulation.

1. A vein is known to be wounded, when dark blood flows in a rapid and uniform stream from the seat of injury.

The **Hæmorrhage** from a wounded vein may, if the vessel be superficial, be arrested by position, and the pressure of a compress, with a few turns of a roller. A wound of one of the larger veins of the trunk—as of the vena cava, innominate, or iliac—will necessarily prove rapidly fatal from uncontrollable hæmorrhage. When one of the large external veins is wounded, such as the internal jugular, the axillary, or the femoral, it should be fairly exposed and tied with catgut ligature above and below the wound in it. Langenbeck has in this case advised that the companion artery should also be tied. And *a priori* it might be supposed that this would be a wise precaution. But experience and the result of statistical inquiries have alike demonstrated its fallacy. Gross and Morris have shown that the ligature of the internal jugular when wounded in operations about the neck or in suicidal attempts is a very safe procedure, whilst if the common carotid be ligatured at the same time, the mortality following the double operation becomes very high. In the extremities also the simultaneous ligature of the main vein and artery is especially apt to lead to gangrene.

A very small puncture in a large vein may be treated by picking up the wall of the vessel at the injured spot, and applying a ligature, so as to include the opening without completely occluding the vein.

A wound in a vein is closed in different ways according to the size of the opening and the mode of treatment. If the vein be completely divided and a ligature applied, the closure of the vein is brought about in the same way as that of an artery under similar circumstances (see Wounds of Arteries). When a wounded vein is treated by pressure, the lips of the wound come in contact with each other, and union takes place without permanent occlusion of the vessel. If a clot forms above and below the point pressed upon, it is absorbed

and the canal of the vessel restored. At the time when venesection was commonly practised, a patient was often bled many times from the same vein during the course of his life without its becoming occluded.

2. *Septic and spreading inflammation of Veins* will be described when we come to speak of the various forms of venous thrombosis and phlebitis; and 3. the *Entrance of Air into Veins* will be discussed in a subsequent chapter.

INJURIES OF ARTERIES.

Arteries may be bruised, torn, punctured, or cut.

CONTUSION.—A slight bruise of an artery is not attended with any bad consequences: but, if the contusion be sufficiently severe to damage the coats, the artery may become plugged with an adherent clot, and finally occluded. This clot may be deposited gradually, so that the obstruction of the vessel may not be complete till some days after the accident. Thus, a patient was admitted into University College Hospital under Mr. Quain, with a contused wound in the axilla, received in falling upon some iron railings; no change took place in the circulation of the arm for two days, when pulsation in the axillary artery ceased, the injured vessel having evidently become plugged by a clot.

RUPTURE AND LACERATION.—An artery may be torn either partially or completely across. When **Partial Rupture** occurs, only the internal and middle coats give way, the toughness of the external coat preventing its laceration. This accident is especially apt to occur in consequence of blows or strains upon diseased or weakened vessels, and may possibly lay the foundation for dissecting and other aneurisms. In other cases, the ruptured portion of the coats becomes turned down into the inside of the vessel, and, acting as a valve, prevents the further progress of the blood through it; more commonly the partially ruptured vessel becomes blocked by a clot adherent to the injured spot. Occlusion of an artery in this way may give rise to gangrene, but as a rule the collateral circulation is sufficient to maintain the vitality of the parts beyond the obstruction. Bowlby has recorded a remarkable case of partial rupture of the subclavian artery resulting from a fracture of the clavicle. The inner and middle coats were cleanly divided at the junction of the first and second parts of the artery, and after being separated from the outer coat in the second part, were driven by the blood-stream into the third part so as completely to occlude it.

A condition of partial rupture may occur in wounds from blunt instruments. Thus, a case occurred at the London Hospital, in which a suicidal wound of the throat had exposed the carotid artery. After death, it was found that the inner and middle coats of the vessel had been divided by the pressure of the knife, which was blunt, but that the external coat had been left entire; and under this was a dissecting aneurism.

The **Complete Rupture** of an artery may occur either in an open wound or under the integuments. When an artery is torn across in an open wound, as in the avulsion of a limb by machinery, or by a cannon-shot, there is usually but little hæmorrhage, even from arteries of the magnitude of the axillary or the femoral, and though the vessel hang out of the wound, pulsating to its very end. The absence of bleeding is owing to the internal and middle coats, which are fragile, breaking off short and contracting

somewhat : while the external coat and the sheath of the vessel, being elastic, are dragged down and twisted over the torn end of the artery, so as completely to prevent the escape of blood (Fig. 121).

When the laceration of the artery is subcutaneous, as occasionally happens in the attempted reduction of an old dislocation of the shoulder, the artery is not as a rule completely torn across, and then either extensive extravasation.

Fig. 121.—Complete Rupture of an Artery.—Vessel laid open. Inner and middle coats broken short. Outer coat drawn out.

or one of the varieties of *Traumatic Aneurism*, to be described in Chapter XV. may be produced.

In **Penetrating Wounds** of an artery, there is always hæmorrhage, unless the puncture be so fine as to be closed by the elasticity of the coats of the vessel. Thus, *Maisonneuve* has shown that an artery may be punctured with a fine needle, without any hæmorrhage resulting. If, however, the puncture be larger than this, being made by a tenaculum or hook, it does not commonly close in this way ; and, if hæmorrhage do not take place immediately, it will probably come on in the course of a few days, from ulceration of the vessel. If the wound be still larger, there is always an amount of immediate hæmorrhage proportionate to its size and to that of the vessel.

The *Direction* of the wound in the artery materially influences its characters. If the cut be parallel to the axis of the vessel, there is less tendency to gaping of the edges than if it be oblique. In transverse wounds of arteries, the retraction of the coats is so great as to cause the wound to assume somewhat of a circular appearance. If the artery be cut completely across, there is always less hæmorrhage than when it is partially divided ; for the retraction and contraction of the cut ends may then be sufficient to close the vessel, whereas they enlarge the aperture when it is merely wounded. When the wound in the artery is subcutaneous, communicating with the surface only by an oblique and narrow aperture, little, if any, external hæmorrhage takes place, but extravasation of blood occurs. The extravasation may either be poured into one of the serous cavities, or it may be diffused in the areolar tissue of the part, infiltrating it extensively, and perhaps by its pressure ultimately producing gangrene ; or it may be effused in a more circumscribed manner, giving rise to one of the forms of traumatic aneurism (see Chapter XV.).

HÆMORRHAGE FROM WOUNDED VESSELS.

LOCAL SIGNS.—The characters of the bleeding or hæmorrhage differ according to the nature of the vessel from which the blood escapes. When a **Vein** is wounded, the blood that is poured out is of a dark colour, and flows in a uniform stream ; the force with which this is projected depending on the conditions in which the wounded vein is placed. If there be any pressure

between the wound and the heart, as of a ligature upon the vessel ; if the position of the part be such as to favour the gravitation of blood towards the wound : or if the muscles of the limb be made to contract—the force of the flow of blood will be increased.

When an **Artery** is wounded, the blood that escapes is of a bright scarlet colour. It flows in jets synchronous with the contractions of the left ventricle ; between the jets the flow does not cease, but the column of blood falls in height. In the great majority of cases the jet comes only from the proximal aperture, dark blood issuing from the distal opening in a continuous and trickling stream ; but in some situations a jet of blood of arterial character may issue from the distal as well as from the proximal end of the cut vessel, as in wounds of the palmar and plantar arches, or of the arteries of the forearm. As the blood flows, the jet lessens in height, in consequence of the weakening of the heart's action. The height and force of the jet in all cases depend greatly on the size of the vessel ; thus the jet from the femoral artery is stronger than that from a muscular branch of the thigh. When a small arterial branch is wounded near its origin from the main trunk, the jet will always be forcible and free ; so also the proximity to the heart will influence materially the force with which the blood is propelled from the wound in the vessel.

Extravasation.—When the blood is not poured out on the surface, but escapes from a wounded vessel into the areolar tissue of a part, the substance of organs, or internal cavities, it is termed an *Extravasation*. In these cases there are not the ordinary local signs of an external hæmorrhage ; but other local phenomena, such as swelling, dulness on percussion, displacement of organs or parts, discoloration of the skin and subjacent areolar tissue, indicate that blood is being poured out subcutaneously ; and we judge of the quantity of the blood that has escaped, not only by the extent of these local phenomena, but by the general effect produced upon the system by its loss.

CONSTITUTIONAL EFFECTS OF HEMORRHAGE.—These depend upon the quantity of blood lost, on the rapidity with which it is poured out, and on the state of the patient's constitution.

When a large quantity of blood is suddenly lost, as when a main artery is cut across or an aneurism bursts, the patient may die forthwith : he falls down in a state of syncope, with a pale cold surface and lividity about the lips and eyes, gasps a few times, sighs, is very restless, and suffers convulsive movements of the limbs before he expires. If the quantity lost be not so great as to produce death, though still very considerable, the patient becomes faint and sick, with coldness and pallor of the surface, profuse perspiration, great restlessness and agitation, thirst, noises in the ears, and failure or complete loss of sight. Although the surface of the body is colder than natural, the patient often complains of feeling hot, and throws off the bed-clothes. The respiration is deep and sighing, and one of the most distressing symptoms is a sensation of want of breath. If the quantity lost, though considerable, be not so great as this, or be spread over a greater interval of time, so that the patient is enabled to rally between the recurrences of the hæmorrhage, a state of *anæmia* will be induced, characterized by pallor of the skin and of the mucous membranes, palpitation of the heart, rushing noises in the head, a tendency to syncope when in the erect position, œdema of the extremities, and general debility.

After excessive loss of blood the patient may gradually rally, and, as the vital fluid is reproduced in his system, he may recover without any bad effects, or he may fall into a state of anæmia, which may perhaps never be completely recovered from, and may be associated with various forms of local debility and disturbance of functions. After very abundant loss of blood, the pulse often assumes a character which has been termed the "hæmorrhagic pulse." Its frequency is greatly increased, the wave of the pulse, as felt at the wrist, is much larger than natural, and diastolic is usually very marked, the coats of the artery being relaxed from want of tone, and the vessel imperfectly filled. At the same time there may be some slight elevation of temperature. The rallying power is greater in young adults than in old people, and greater in women than in men. Children bear loss of blood badly—a very small hæmorrhage may induce fatal syncope in infants. In advanced life blood is slowly reproduced; and a great loss, whether by accident or in an operation, is seldom completely recovered from, and predisposes to the development of secondary diseases of various kinds. As has already been stated at p. 15, it is in this way that excessive loss of blood at an operation, as for stone in an aged man, may indirectly prove fatal.

Arterial hæmorrhage is, as a rule, more dangerous than venous, as the loss of blood is more rapid and sudden, and the effect produced is proportionally greater. The body of a person who has died from the effects of hæmorrhage presents a peculiarly blanched, semi-transparent, waxen look; the lips, ale of the nose, and finger-nails, have a somewhat livid appearance, contrasting strongly with the clear, yellowish-white hue of the general surface.

TREATMENT.—The *General Treatment* of hæmorrhage is sufficiently simple. After the flow of blood has been arrested by proper local means, such as will hereafter be described, the effects of its loss are usually speedily recovered from under the influence of rest and good nourishment. In some cases, however, the health becomes permanently impaired, and a state of chronic anæmia is induced, which, notwithstanding the administration of preparations of iron, may continue through life.

When the loss of blood is considerable, it may be necessary to have recourse to immediate measures in order to prevent the syncope from being fatal. With this view the patient should be laid recumbent, with the head low and the limbs raised; pressure may be exercised upon the abdominal aorta or the main arteries of the limbs, or Esmarch's elastic bandage and tourniquet may be applied, so as to confine the blood as much as possible to the head and trunk, and thus maintain a good supply to the brain and lungs. If death appear imminent as happens in some cases of flooding, recourse may be had to transfusion of blood or other fluids; the influence of this, in restoring the failing powers of the heart and nervous system, is immediate and most striking, and its value has been sufficiently proved by the observations of many surgeons and obstetricians.

Operation of Transfusion.—Although there is reason to believe that Transfusion of Blood was not unknown to the ancients, and the method by which it could be performed was distinctly described by Libavius in 1615, little was done in the matter until Sir Christopher Wren, in 1657, proposed and practised the operation of injecting medicated liquids into the veins of animals. Transfusion was first performed on man in France, by Denis and Esmarch, on June 15, 1667. In November of the same year, it was done

in this country by Lower and King. In the early experiments, the blood of sheep and calves was used. The most extravagant ideas were formed as to the utility of transfusion. It was supposed to be capable of curing diseases by substituting the blood of a healthy animal for that of a diseased person, of removing insanity by the injection of the blood of animals of a gentle and docile character into the veins of a maniac, and of prolonging life indefinitely. These pretensions led to a scientific controversy of the most violent kind ; and, some deaths having occurred from the practice, partly in consequence of the rude and imperfect instruments used, transfusion was prohibited in France, and fell into disrepute in England. Although the subject was occasionally revived, little attention was paid to it until 1824, when transfusion was again practised by Blundell, who wisely restricted its employment to those cases, chiefly occurring in obstetric practice, in which, in consequence of sudden and profuse hæmorrhage, the patient is threatened with fatal syncope.

The transfusion of defibrinated blood was recommended by Panum, of Copenhagen, in 1863 as a means of diminishing the risk of the introduction of clots into the circulation. According to Bergmann the febrile disturbance which may follow is due to the excess of fibrin ferment set free during coagulation.

The danger of the transfusion of the blood of the lower animals was recognised early in this century. Experiments have shewn that the corpuscles break up rapidly, and that hæmaturia and extensive capillary embolism may result. As a means of preventing the occurrence of embolism, it has been suggested that a mixture of blood and 5 per cent. solution of phosphate of sodium should be used instead of pure blood.

The transfusion of blood was founded on the belief that death from hæmorrhage resulted from a loss of red corpuscles and hæmoglobin. Goltz, however, shewed the fallacy of this view and recognized the important fact that the fatal result is consequent upon an extensive loss of fluid from the vascular system, and thus it became evident that the transfusion of blood, with all its dangers and difficulties, could be replaced by the injection of a sufficient quantity of any suitable fluid, such as a simple saline solution. The present views on this subject were fully expressed by Dr. William Hunter in his lectures at the Royal College of Surgeons in 1889. They are as follows :—first, that the immediate source of danger from sudden loss of blood is the rapid fall of blood pressure ; secondly, that the value possessed by transfused blood is almost solely *physical* and dependent upon its volume ; and lastly, that all the advantages of transfused blood can be more readily and safely obtained by the use of simple saline solution.

Transfusion is best adapted to extensive and sudden losses of blood from small wounds of large vessels, or from secondary hæmorrhage. It has also proved of the greatest value in obstetric practice. Transfusion after serious surgical operations, such as the removal of large vascular tumours, amputation of the hip, and the like, has seldom proved of material service. The cause of death in such cases is severe shock and not mere loss of blood. The intravenous injection of saline solutions in such cases does, however, seem worthy of further trial, and recently Mayo Robson has recorded two instances in which severe shock following operations not attended with much loss of blood was successfully treated by the intravenous injection of three or four pints of simple saline solution. If transfusion be determined on, it should not be

delayed until the last moment, when the agony of death has already commenced: for then the functions of the nervous and circulatory systems may be so impaired that the patient is beyond recovery, or, if he can be temporarily restored, he will speedily relapse and die.

Transfusion of blood has been carried out directly and indirectly. In the former method a direct communication is established between the vein of the donor and that of the recipient. Aveling's apparatus for this purpose has the great advantage of simplicity; it consists of an india-rubber bulb on the middle

Fig. 122.—Apparatus for Intravenous Injection of Saline Solution.

of a tube, the ends of which are attached to silver bevel-ended cannulae inserted into the vein of the donor and recipient respectively. The ingenious apparatus devised by Dr. Roussel, of Geneva, is too complicated to be of much practical use.

Mediate or indirect transfusion with defibrinated blood has been performed with an ordinary aspirator syringe.

Intravenous Injection of Salt Solution may be performed in the following manner, and ordinary antiseptic precautions should be observed. The solution consists of one drachm of sodium chloride dissolved in one pint of boiled distilled water. A bottle of the form represented in Fig. 122, and large enough to hold two pints, is filled with the solution, and the temperature of the latter is kept at 105° Fahr. by placing the bottle in a vessel of hot water. The median basilic or median cephalic vein is exposed and ligatured at the lower end of the incision. The vein is then opened above the ligature by picking it up with forceps and snipping it half across obliquely with a scalpel or scissors. The cannula is introduced (Fig. 123) and tied with a fine silk ligature. Great care must be taken that the tube and cannula are full of the solution, lest air enter the vein. By slightly raising the bottle the fluid is allowed to flow slowly, and the effect is carefully watched. The amount of fluid required varies greatly

Fig. 123.—Introduction of Cannula into Vein.

in different cases, but between one and two pints is usually sufficient. Very much larger quantities have, however, been used with satisfactory results, and the Surgeon must in each case be guided by the effect produced upon the pulse and the general condition of the patient. In the absence of the apparatus above described, the injection can be performed with a syringe, or with a simple siphon like that used for the nasal douche.

CHAPTER XIV.

ARREST OF ARTERIAL HÆMORRHAGE.

THE arrest of arterial hæmorrhage is perhaps the most important matter that can engage the Surgeon's attention, for on the accomplishment of this the success of every operation is necessarily dependent. In studying this subject we must first consider the Means adopted by Nature for the Suppression of Hæmorrhage; and, secondly, the imitation of these by Surgical Art.

NATURAL ARREST OF HÆMORRHAGE.

The history of the investigations into the means adopted by nature for the arrest of hæmorrhage is full of interest to the Surgeon, and is excellently given in J. F. D. Jones's work on Hæmorrhage. No subject in surgery affords stronger evidence of the advantage of the application of "Experimental Pathology" to practice than this, as our knowledge of it has been wholly gained by experiments on the lower animals; and by the sacrifice of the lives of a few dogs, donkeys, and calves, those of hundreds—probably of thousands—of human beings are annually preserved.

Petit, who published several memoirs on the subject in 1731 and following years, stated that hæmorrhage was arrested by the formation of two clots—one outside the vessel, which he called the "*Couvercle*," or Cover; the other inside, the "*Bouchon*," or Plug—the former being formed by the last drops of blood that issue, the latter by that within the vessel. These clots, he said, by their adhesion to the internal coat of the vessel and to the orifice stopped the bleeding. When a ligature is applied, a similar clot forms above it. He recommended compression, and the support of the clot.

Morand, in 1736, added much of interest. He admitted the formation of coagula, but insisted on the importance of the changes in the artery itself; which, he showed, became corrugated, contracted, and retracted. Morand entertained erroneous views as to the structure and functions of arteries, but he established the great fact that changes occur in the artery itself. Sharp, in the second edition of his work on Operative Surgery, published in 1739, supported the same doctrine.

Kirkland, in 1763, wrote an excellent treatise on the subject. He showed that hæmorrhage was lessened by swooning, and that an artery contracted up to its nearest collateral branch; and he was of opinion that the coagulum did not arrest the bleeding. His views were adopted and supported by White, Lough, Aikin, and other surgeons of his day.

J. Bell took a retrograde step by denying the retraction and contraction of the artery, and the importance of the internal coagulum, and by attributing the arrest of hæmorrhage solely to the injection of the surrounding areolar tissue with blood.

It was not until 1805, that Jones, by a series of admirably conducted investigations, finally determined the mode in which the arrest of hæmorrhage takes place.

The *Natural Arrest of Arterial Hæmorrhage* is effected by means that in the first instance are *temporary*, but afterwards *permanent*.

TEMPORARY MEANS.—The means which temporarily arrest the flow of blood from an artery are threefold. If the vessel be small, as the facial or radial, these means are sufficient in many cases to stay the hæmorrhage without the interference of the Surgeon: and, whatever be the size of the vessel, his operations are materially assisted by the efforts which Nature makes, though they may sometimes be unsuccessful to prevent a fatal escape of blood. They consist in:

1. The **Coagulation of, and an Alteration in, the Constitution of the Blood.**
2. A **Diminution of the Force of the Heart's Action;**
3. Certain **Changes produced in and around the Artery.**

1. The **Coagulation of the Blood** in and around the wounded artery is the most important means adopted by Nature for the arrest of hæmorrhage. Were it not for the property of coagulation, the blood would continue to drain away from any cut artery, however small, until life became extinct. But the coagulation of the blood is sufficient, in all arteries below a certain size, to close the opening in the vessel, and so to arrest the further escape. The *Alteration that takes place in the Blood*, as was first pointed out by Hewson, consists in an increase of its coagulability as it flows.

2. The **Diminution in the Force of the Heart's Action**, owing to the patient becoming faint, exercises a very material influence in arresting the flow of blood from an artery. The forcible manner in which the jet of blood is propelled at each systole of the ventricle, is the principal obstacle to the formation of an adherent blood-clot around and within the cut vessel; for so long as the jet is more powerful than the cohesion of the clot, it will certainly wash the coagulom away. As the blood flows, and the heart's impulse gradually lessens in force, the jet falls lower and lower; until at last, when faintness comes on, it is almost entirely arrested, and time is afforded for the deposit of a coagulum in the vicinity of the wound. The collapse consequent on excessive and sudden loss of blood may therefore be looked upon as one of the provisions of Nature for the safety of the patient, and should not be too speedily counteracted by stimulants or in any other way.

3. The **Changes that take place in and around the Vessel itself** are those upon which the final arrest of the bleeding is dependent. They consist in the *Retraction* of the artery within its sheath, in the *Contraction* of the cut ends, and in the *Formation of a Coagulum* around its exterior, and in its interior.

When an artery is cut across, its longitudinal elasticity causes it immediately to *retract within its sheath*, and at the same time its orifice is narrowed by the *contraction of the muscular fibre cells of the middle coat* in consequence of the stimulation of the mechanical violence. As the artery retracts, the interior of the sheath is left rough and uneven. Through this uneven channel the blood is projected, and as it flows over the roughened surface of the sheath, it is entangled in the fibres, and tends to coagulate upon them; thus the tendency to coagulation is favoured by the increased plasticity of the blood as it flows, and by the diminution of the propulsive force with which it is carried

on. By the conjoined operation of these causes a coagulum is formed, which, though lying within the sheath, is outside the artery, and extends beyond it: and is hence termed the **external coagulum**. It is usually somewhat cylindrical, and often looks like a continuation of the vessel, being at first perforated by a hollow track, through which the stream of blood continues to flow. As it increases in size, the track becomes closed by the concentric deposit of coagulum. The hollow track leading from the surface of the coagulum to the wound in the artery, has been especially described and dwelt upon by Amussat. This coagulum acts mechanically by blocking up the end of the artery, and thus constitutes the first barrier to the hæmorrhage.

Simultaneous with the changes that have just been described is the **contraction** of the cut artery which commences immediately after its division, and may of itself be sufficient to close a small vessel. Thus, during an operation, we may often see the mouth of an artery which, when first cut, spouted out a stream of blood as large as a straw, gradually diminish in size until it ceases to bleed, owing simply to this contraction. In a larger artery this process is not sufficient completely to close the vessel, but merely gives its cut end a conical shape and greatly diminishes the aperture in the artery.

The next change that takes place is the formation of the **internal coagulum**. As the open end of the artery becomes obstructed by its own contraction and by the formation of the external coagulum, the blood is propelled with more and more difficulty through it, escaping in a small and feeble stream, and at last becoming completely stationary. Coagulation then takes place within the artery, and the clot that is formed in this situation plays a prominent part in the permanent closure of the vessel. The internal coagulum is conical in form, the base being firmly adherent to the injured coats of the artery at the margin of the aperture and the apex extending upwards. It has no point of attachment except by its base, the apex and sides being perfectly free: at first it consists merely of ordinary blood-clot, but later on, as will be seen hereafter, it undergoes important changes. The importance of the internal coagulum as a temporary means of arresting hæmorrhage, though great, has, I think, been overestimated. In fact it is not formed until the flow of blood has been arrested by the contraction of the artery and the formation of the external clot; and in some cases the proximity of a collateral branch to the cut end of the vessel appears, by preventing the stagnation of the blood, to prevent its formation altogether. When it is formed, it is useful in acting as a damper to break the force of the wave of blood against the cut end of the vessel. The contraction of the artery, being due to the action of the muscular coat, must necessarily cease before long, when relaxation of the muscular fibre-cells takes place; but by this time the vessel is surrounded externally by a coagulum between the sheath and the external coat. This clot having been moulded to the artery in its contracted state prevents the dilatation that would otherwise occur.

After the hæmorrhage from the cut artery has been arrested temporarily by the means that have been indicated, the process of permanent occlusion commences.

PERMANENT CLOSURE of a cut artery is effected by processes analogous to those which have already been described as occurring in the union of wounds in the Chapter on the Process of Repair (p. 286 *et seq.*). During the first few hours after the arrest of the bleeding, the internal coagulum contracts slightly

and becomes more adherent to the inner coat of the artery. For the first twenty-four hours or more the ordinary process of exudation with migration of the white corpuscles takes place, both from the vasa vasorum of the injured artery and from the vessels in the sheath. By the second day therefore we find that the base of the internal coagulum and the external coagulum in the sheath have become paler in colour from infiltration with migrated leucocytes; and exactly opposite the divided end of the artery there may be a small nodule of colourless plastic exudation, composed entirely of small round cells held together by coagulated fibrin. This change therefore corresponds to that which has already been described as occurring in the early stages of union of wounds by first intention, the only difference being in the presence of the great excess of blood-clot. By the end of the first twenty-four or thirty-six hours, if all goes well, the process of the traumatic inflammation and the accompanying exudation resulting from the wound should have ceased, and we then have a firm mass of plastic exudation plugging the mouth of the artery and surrounding its cut extremity externally, and the processes of genuine repair now set in. Outside the vessel these consist merely of the vascularization of the "plastic exudation," the absorption of the blood-clot, and the gradual development of cicatricial fibrous tissue, as already described (p. 288 *et seq.*). It is evident that if these processes go on undisturbed by further inflammation and exudation, the orifice of the wounded vessel is from the first surrounded externally by a firm substance—first, blood-clot; secondly, plastic exudation or "coagulable lymph;" thirdly, firm vascular granulation-tissue; and, lastly, fibrous scar tissue. The artery is therefore sealed externally as well as internally, and these external changes are of equal importance with those about to be described as occurring inside the vessel. If inflammation and suppuration take place in the wound from any cause, more especially if decomposition of the discharges sets in with breaking down of the external coagulum, thus causing the presence of septic matter in immediate contact with the end of the wounded artery, the injured vessel is no longer supported externally, and the safety of the patient will wholly depend upon the changes occurring within the vessel.

We have already seen that soon after its formation the base of the internal coagulum becomes infiltrated with exudation from the vessels of the injured coats of the artery, and consequently becomes paler in tint than the rest of the clot. The internal coagulum gradually extends further from the injured part of the vessel till, as a rule, it reaches the nearest branch above. The next change observed in the clot is that it shrinks slightly. The artery also contracts, firmly embracing the coagulum. The clot now becomes firmly adherent in every part to the inner coat till some difficulty may be experienced in separating it. The contracted vessel usually assumes a conical shape; but in some cases I have seen the contraction commence suddenly, the narrowed part being perfectly cylindrical for about an inch. The next change observable is the *decolorization of the clot*. This commences at the part which is in contact with the injured end of the vessel and gradually extends upwards. The red corpuscles in the clot break up and are absorbed.

Firm fibrinous plug closely adherent to the inner coat of the artery.

of decolorization is accompanied by still further shrinking of
is usually completed in about a week. The ultimate changes

consist in a gradual absorption of the internal coagulum, with development of cicatricial fibrous tissue for a greater or less distance from the divided end, the artery being for a corresponding distance converted into a dense fibrous cord. In some cases the complete obliteration of the vessel reaches as high as the next branch; but in others an extremely narrow channel may be found extending some distance into the contracted part of the vessel.

If these processes be followed microscopically in specimens obtained at different periods from animals, the following appearances may be observed: The first exudation which forms at the cut end of the artery and infiltrates the base of the clot differs in no respect from the early exudation in union of a wound by first intention; it is composed of migratory white corpuscles entangled in the meshes of coagulated fibrin. This exudation commences immediately after the injury. By the third day the base of the clot will be more extensively decolorised and the microscope shows that this is due to the growth of new cells which have occupied the place previously filled by the lower part of the clot. The origin of these new cells has been a matter of dispute. Those which infiltrated the base of the clot in the first twenty-four hours are undoubtedly migratory corpuscles; but it seems probable that as soon as the artery has recovered from the damage done it by the wound, growth commences from the endothelial cells of the inner coat. These are described by Cornil and Ranvier as multiplying rapidly and penetrating into the substance of the clot.

The investigations of Ballance and Edmunds give strong support to this view. These observers find that in the carotid of the rabbit proliferation of the endothelial cells can be demonstrated as early as twenty-four hours after the application of a ligature to the vessel. Proliferation was also found to occur in the other connective-tissue cells of the arterial wall; the elastic lamina being eventually broken up by the multiplication and migration inwards of the cellular elements of the middle coat. The coagulum is thus slowly absorbed and replaced by a mass of cells, which are partly migrated leucocytes, but chiefly "plasma-cells" derived from the endothelial and other connective-tissue cells of the arterial wall. By the end of a few days the new tissue replacing the clot is in direct contact with the elastic layers of the inner coat. The mass of cells thus formed is soon penetrated by new vessels springing from the vasa vasorum of the artery at the wounded part. The further course of development is identical with that already described in the chapter on Repair, occurring in the conversion of vascular "granulation-tissue" into cicatricial fibrous tissue. The final result of the process is that the lumen of the artery for a variable distance becomes filled with fibrous tissue continuous with the coats of the vessel. The development of the cicatricial tissue from the granulation-tissue is necessarily accompanied by considerable contraction, while at the same time the muscular coat atrophies from want of use; and thus after some weeks or months the end of the artery becomes converted into a thin cord of fibrous tissue, which is finally lost in the scar of the external wound.

This development of fibrous tissue in the site of the clot has been described as "organisation of the thrombus." This term is, however, somewhat misleading, and it must be clearly understood that, according to the views held by modern pathologists, the thrombus takes no more share in the production of the fibrous tissue than does the layer of blood-clot which cements together the

After excessive loss of blood the patient may gradually rally, and, as the vital fluid is reproduced in his system, he may recover without any bad effects, or he may fall into a state of anemia, which may perhaps never be completely recovered from, and may be associated with various forms of local debility and disturbance of functions. After very abundant loss of blood, the pulse often assumes a character which has been termed the "hæmorrhagic pulse." Its frequency is greatly increased, the wave of the pulse, as felt at the wrist, is much larger than natural, and diastolic is usually very marked, the coats of the artery being relaxed from want of tone, and the vessel imperfectly filled. At the same time there may be some slight elevation of temperature. The rallying power is greater in young adults than in old people, and greater in women than in men. Children bear loss of blood badly—a very small hæmorrhage may induce fatal syncope in infants. In advanced life blood is slowly reproduced; and a great loss, whether by accident or in an operation, is seldom completely recovered from, and predisposes to the development of secondary diseases of various kinds. As has already been stated at p. 15, it is in this way that excessive loss of blood at an operation, as for stone in an aged man, may indirectly prove fatal.

Arterial hæmorrhage is, as a rule, more dangerous than venous, as the loss of blood is more rapid and sudden, and the effect produced is proportionally greater. The body of a person who has died from the effects of hæmorrhage presents a peculiarly blanched, semi-transparent, waxen look; the lips, alæ of the nose, and finger-nails, have a somewhat livid appearance, contrasting strongly with the clear, yellowish-white hue of the general surface.

TREATMENT.—The *General Treatment* of hæmorrhage is sufficiently simple. After the flow of blood has been arrested by proper local means, such as will hereafter be described, the effects of its loss are usually speedily recovered from under the influence of rest and good nourishment. In some cases, however, the health becomes permanently impaired, and a state of chronic anemia is induced, which, notwithstanding the administration of preparations of iron, may continue through life.

When the loss of blood is considerable, it may be necessary to have recourse to immediate measures in order to prevent the syncope from being fatal. With this view the patient should be laid recumbent, with the head low and the limbs raised; pressure may be exercised upon the abdominal aorta or the main arteries of the limbs, or Esmarch's elastic bandage and tourniquet may be applied, so as to confine the blood as much as possible to the head and trunk, and thus maintain a good supply to the brain and lungs. If death appear imminent as happens in some cases of flooding, recourse may be had to transfusion of blood or other fluids; the influence of this, in restoring the failing powers of the heart and nervous system, is immediate and most striking, and its value has been sufficiently proved by the observations of many surgeons and obstetricians.

Operation of Transfusion.—Although there is reason to believe that Transfusion of Blood was not unknown to the ancients, and the method by which it could be performed was distinctly described by Libavius in 1615, little was done in the matter until Sir Christopher Wren, in 1657, proposed and practised the operation of injecting medicated liquids into the veins of animals. Transfusion was first performed on man in France, by Denis and Emmerez, on June 15, 1667. In November of the same year, it was done

in this country by Lower and King. In the early experiments, the blood of sheep and calves was used. The most extravagant ideas were formed as to the utility of transfusion. It was supposed to be capable of curing diseases by substituting the blood of a healthy animal for that of a diseased person, of removing insanity by the injection of the blood of animals of a gentle and docile character into the veins of a maniac, and of prolonging life indefinitely. These pretensions led to a scientific controversy of the most violent kind : and, some deaths having occurred from the practice, partly in consequence of the rude and imperfect instruments used, transfusion was prohibited in France, and fell into disrepute in England. Although the subject was occasionally revived, little attention was paid to it until 1824, when transfusion was again practised by Blundell, who wisely restricted its employment to those cases, chiefly occurring in obstetric practice, in which, in consequence of sudden and profuse hæmorrhage, the patient is threatened with fatal syncope.

The transfusion of defibrinated blood was recommended by Panum, of Copenhagen, in 1863 as a means of diminishing the risk of the introduction of clots into the circulation. According to Bergmann the febrile disturbance which may follow is due to the excess of fibrin ferment set free during coagulation.

The danger of the transfusion of the blood of the lower animals was recognised early in this century. Experiments have shewn that the corpuscles break up rapidly, and that hæmaturia and extensive capillary embolism may result. As a means of preventing the occurrence of embolism, it has been suggested that a mixture of blood and 5 per cent. solution of phosphate of sodium should be used instead of pure blood.

The transfusion of blood was founded on the belief that death from hæmorrhage resulted from a loss of red corpuscles and hæmoglobin. Goltz, however, shewed the fallacy of this view and recognized the important fact that the fatal result is consequent upon an extensive loss of fluid from the vascular system, and thus it became evident that the transfusion of blood, with all its dangers and difficulties, could be replaced by the injection of a sufficient quantity of any suitable fluid, such as a simple saline solution. The present views on this subject were fully expressed by Dr. William Hunter in his lectures at the Royal College of Surgeons in 1889. They are as follows :—first, that the immediate source of danger from sudden loss of blood is the rapid fall of blood pressure : secondly, that the value possessed by transfused blood is almost solely *physical* and dependent upon its volume ; and lastly, that all the advantages of transfused blood can be more readily and safely obtained by the use of simple saline solution.

Transfusion is best adapted to extensive and sudden losses of blood from small wounds of large vessels, or from secondary hæmorrhage. It has also proved of the greatest value in obstetric practice. Transfusion after serious surgical operations, such as the removal of large vascular tumours, amputation at the hip, and the like, has seldom proved of material service. The cause of death in such cases is severe shock and not mere loss of blood. The intravenous injection of saline solutions in such cases does, however, seem worthy of further trial, and recently Mayo Robson has recorded two instances in which severe shock following operations not attended with much loss of blood was successfully treated by the intravenous injection of three or four pints of simple saline solution. If transfusion be determined on, it should not be

thumb. Thus, in amputation at the hip or shoulder joint, the assistant readily controls the rush of blood from the femoral or axillary artery by grasping them between his fingers. Above all, the Surgeon should never dread hæmorrhage, nor lose his presence of mind when it occurs. If recourse be had to proper means, it can always be, at least temporarily, arrested. On no account should anyone who pretends to the character of a Surgeon employ inefficient means to stop it, and imagine that he can, by covering up the wound with rags, handkerchiefs, &c., prevent the escape of blood. These procedures only hide the loss that is going on, and, by increasing the warmth of the parts, prevent the contraction of the vessels, and favour the continuance of the bleeding. Under all circumstances, therefore, bleeding wounds should be opened up, the coagula gently removed from their surface by means of a piece of soft sponge or a stream of cold water, and the part well cleaned. In this way "you look your enemy in the face," and can adopt efficient means for the permanent arrest of the hæmorrhage.

The methods of controlling the flow of blood temporarily by digital compression and by the various forms of tourniquet have been fully described on p. 45 *et seq.* It is usually necessary to have recourse to some of these during the application of means intended to produce permanent arrest of the bleeding. The screw tourniquet and digital compression will usually be found the most convenient, as the pressure can be rapidly relaxed, in order to guide the Surgeon to the bleeding-point, and reapplied if necessary.

The different means that may be employed for the *permanent* arrest of hæmorrhage are : 1, The Application of Cold ; 2, the Application of Hot Water ; 3, Styptics ; 4, Canterisation with a Hot Iron ; 5, Pressure ; 6, Flexion ; 7, Torsion ; 8, Forcepressure ; 9, Ligature ; and 10, Acupressure.

1. APPLICATION OF COLD is sufficient to arrest the general oozing of arterial blood which is always observed on a cut surface. The mere exposure to the cold air of a wound, which has bled freely so long as it has been covered up by pledgets and bandages, is often sufficient. When this does not succeed, the application of a piece of lint, soaked in cold water, will usually arrest the flow of blood. In cases of bleeding into some of the cavities of the body, as the rectum, vagina, or mouth, the application of ice is advantageous. Its use should not, however, be too long continued, lest sloughing occur. Indeed, if cold do not speedily arrest the bleeding, it is better to have recourse to more efficient means.

2. The APPLICATION OF HOT WATER is a most valuable means of arresting oozing during or immediately after an operation. It is especially useful in operations about the face and trunk in which it is impossible to adopt any bloodless method of operating, and yet in which it is important that the view of the operator should not be obscured by persistent oozing of blood. It immediately arrests the free bleeding from small vessels which follows the removal of Esmarch's bandage. This mode of treatment was introduced in America in 1879 by Hamilton, Brown, and Hunter. Hamilton applied water at a temperature of between 150° F. and 160° F., by means of sponges held in forceps. Brown recommended washing the whole wound with water of the same temperature. Hunter applied the water at a lower temperature, 125° F. to 130° F., which can just be endured by the Surgeon's hands. All these plans act very well, and although the heat is sufficient to whiten the surface of a divided muscle, no evil consequence results, and union by first intention is

not interfered with. If the wound is being treated antiseptically, a hot solution of carbolic acid (1 in 40), or two teaspoonfuls of tincture of iodine added to a pint of water, may be used instead of the simple hot water. Care must be taken in employing this method of arresting hæmorrhage, that the water used be sufficiently hot, otherwise the effect will be merely to increase the bleeding.

Some very interesting observations by Milne Murray have clearly shown the superiority of hot water to cold in inducing contraction of involuntary muscular fibre. They may be briefly summarised as follows: After the application of cold, there is a very distinct latent period, and contraction develops slowly, while hot water at a temperature of 110° F. to 120° F. gives rise to almost immediate contraction rapidly developed. Successive applications of cold induce contraction only after a period of rest, and the contractions become diminished in efficiency; successive applications of heat, on the other hand, are followed by immediate contraction, and the efficiency of the contraction is increased rather than diminished. Continuous application of cold produces rapid exhaustion, the muscular fibre becoming completely relaxed and failing to respond, while heat induces a high degree of contraction, broken by periods of partial relaxation followed again by contraction. In Murray's experiments the uterus of the rabbit was chiefly used, but there is no doubt the results may be applied equally to the muscular tissue of arteries.

3. STYPTICS are substances which cause contraction of the vessels and coagulate the albumen of the blood, thus increasing the rapidity of formation and the firmness of the coagulum. They are used principally in oozing from spongy parts, or in bleeding from cavities or organs to which other applications cannot readily be made. The great objection to their employment in some wounds is their tendency to modify injuriously the character of the surface and to prevent union by the first intention. The most useful styptics are the solution of perchloride of iron, spirits of turpentine, and gallic or tannic acid; the application of alum, or touching a bleeding part with a pointed stick of the nitrate of silver, is also serviceable. Of all these, the solution of the perchloride of iron is that most commonly used, and it is undoubtedly a most powerful hæmostatic, but it acts very injuriously on the wound. The black hard clot it forms with the blood is very efficient in arresting the bleeding, but is slow to come away and delays healing. Turpentine is a most valuable styptic. It was formerly much used, and is now too much neglected. It is antiseptic and does little damage to the surfaces of the wound. It should always be tried when possible before using the perchloride of iron. In some cases tincture of hamamelis (3j. or 5j. to 3j.) will be found an efficient hæmostatic. *In order to apply any styptic effectually, the wound should be thoroughly cleaned, and all coagula removed.* A piece of lint or absorbent cotton-wool, or a sponge squeezed as dry as possible, is then firmly pressed on the bleeding spot by an assistant, or by the Surgeon with his left hand, while another piece of lint or cotton-wool is soaked in the styptic solution, and then squeezed nearly dry. The piece of dry lint or sponge is rapidly removed from the wound with the left hand, and the styptic instantaneously applied with the right before the surface has had time to get wet with blood. It may then be maintained in position by the pressure of the finger or of a pad and bandage. When the hæmorrhage is from a cavity and the actual bleeding point cannot be seen, the styptic solution may be injected by means of a

syringe, or, in some cases, if it proceed from a mucous canal, this may be firmly plugged with lint soaked in the styptic solution.

Wright has suggested the use of what he calls a "physiological styptic." It consists of an extract of calf's thymus with a weak solution of carbonate of soda, to which 1 per cent. of chloride of calcium is added. The active agent is Wooldridge's tissue fibrinogen.

4. CAUTERISATION by means of the red-hot iron was the mode of arresting arterial hæmorrhage most used by the ancients and in the Middle Ages. It is now comparatively seldom employed, and should never be made use of where less severe measures are likely to succeed. Yet in some cases it is of great utility, and superior to any other means that we possess; more particularly when the hæmorrhage proceeds from a soft and spongy part that will not hold a ligature, or on the surface of which many points appear to be bleeding at the same time. A somewhat conical iron of sufficient size should be used, and the hæmorrhage will often be checked more effectually if it be applied at a black than at a red or white heat. The bleeding surface must be carefully dried by the pressure of a sponge or of dry cotton-wool before the cautery is applied, otherwise its action is extremely uncertain. It is most useful, perhaps, for the arrest of capillary hæmorrhage from sloughing wounds, but arteries of moderate size may thus be closed. As the actual cautery blocks up the artery with a thick slough or eschar (Fig. 124), there is

FIG. 124. A fresh Artery from the head body, cauterised, showing the firm adherent eschar.

always some danger of a recurrence of the bleeding when this separates, and the Surgeon must be on his guard about the sixth or eighth day lest the hæmorrhage break out afresh.

In some cases, however, in which the cautery has been applied to the cut end of an artery removed from a fresh dead body, it has been found that the eschar is formed of the external coat only, the inner and middle coats being separated and turned up into the lumen of the artery. This result, however, does not seem to be constant.

The actual cautery has frequently been employed of late years during operations on very vascular parts in which temporary arrest of the circulation is impossible. It has been used chiefly in two forms: first as the galvanic *écraseur*, and secondly as a red-hot knife. The galvanic *écraseur* is simply a loop of platinum-wire which can be heated by electricity after being passed round the part to be removed. During the operation the loop is gradually tightened, by means of a screw in the handle of the instrument, until the part is removed. Operations performed in this way are almost bloodless; but the instrument, with its battery, is very cumbersome, its action is not certain, and secondary hæmorrhage is common after its use; consequently it is now but little employed except for the removal of nasal polyp and other small pedunculated growths. Its place has been taken in larger operations by Paquelin's red-hot knife. This is a flattened hollow blade with blunt edges, made of platinum, and fixed on a handle connected by an india-rubber tube with a bottle containing benzol. The knife is first made red-hot in a spirit lamp, and its heat is maintained by blowing a mixture of air and benzol-vapour into the hollow blade by means of an elastic ball. The benzol-vapour burns without flame, and the heat can be maintained at any point that is required by driving in a larger or smaller amount of vapour. Care must be taken not to allow any of the liquid benzol

to get into the tube, or a flame would flash from the instrument : this is best avoided by filling the bottle with pieces of sponge. The blade can be replaced if necessary, by cauteries of various shapes. In removing very vascular growths, such as an epithelioma of the vulva, the knife, if at a glowing red heat, arrests the flow of blood from the smaller vessels only, leaving the larger arteries spouting from a perfectly dry surface, and they can thus be seized and tied without difficulty, or, if preferred, touched with the cautery at a dull red heat. The surface left is very superficially charred, and heals with little or no sloughing. If it be desired to arrest the flow of all vessels completely, the knife must be used at a dull red heat ; it then cuts more slowly and chars more deeply.

5. DIRECT PRESSURE upon the bleeding part is a very efficient mode of arresting hæmorrhage from small arteries. It is not, however, equally applicable to all parts of the body. It can be most readily applied when the vessel has a bone subjacent to it, so as to afford a point of counterpressure, and it cannot be so readily employed in soft and movable parts, as the throat or perinaeum. Pressure may be practised in various ways. Sometimes the uniform compression of a bandage is sufficient ; thus oozing from an amputation wound may often be stopped by laying down the flaps and applying a bandage firmly over them. In the cotton-wool dressings the elastic pressure is of great use in arresting oozing. In the case of bleeding from hollow cavities, as the rectum, vagina, or nares, the hæmorrhage may be arrested by the pressure of a plug of sponge or lint, to which sometimes a styptic may advantageously be added. When the hæmorrhage proceeds from the puncture of a small or moderate-sized artery, as the temporal, pressure should be made against the subjacent bone by means of a graduated compress and bandage, and should be continued until a sufficient time has elapsed for the vessel to be firmly plugged on each side by an adherent coagulum. The *graduated compress* should be at least an inch in thickness, and made of a series of pledgets of lint of a circular shape, gradually diminishing in size. It should be applied with its pointed end resting over the wound in the vessel. Care should be taken that the part on which the pressure is to be exercised has been thoroughly dried of all blood, and that the artery is commanded on the proximal side of the wound by a tourniquet or by the pressure of an assistant's finger. A thick shoe of a phial-cork, or a threepenny piece, wrapped in lint, being placed on the wound, the graduated compress should be bandaged tightly over the whole. When applied in this way, pressure acts by encouraging the formation of an adherent clot on each side of the part of the vessel closed by the force applied. The subsequent changes are the same as those already described as occurring after spontaneous arrest of bleeding (p. 414).

Whenever pressure is used to arrest arterial bleeding, it must not be forgotten that the whole area pressed upon is rendered absolutely bloodless. We have before seen (p. 175), that if a part be deprived of blood for a sufficient time—probably in the human subject for between twelve and twenty-four hours—the readmission of blood is accompanied by all the phenomena of acute inflammation, the intensity of the process varying with the length of time during which the part has been kept bloodless ; and we are all of course familiar with the fact that, if the pressure be applied with sufficient force for a sufficient length of time, death of the part must follow. It is very important, therefore, that pressure should not be applied for a single hour longer than

is necessary to ensure the safe plugging of the wounded artery by an adherent clot. The experience of acupressure has shown us that in a small artery—and it is, of course, only to small arteries that pressure is applied as a means of arresting hæmorrhage—about twelve hours is a sufficient time to ensure the closure of the vessel. *A graduated compress should, therefore, not be kept firm applied for more than twelve hours*; at the end of that time the bandages should be removed and loosely reapplied without disturbing the compress, which will be sticking to the part, after which the patient must be kept very quiet with the limb raised if the wound be in one of the extremities. The inflammation or sloughing produced by excessive and prolonged pressure is the cause of the frequency with which arrest of bleeding by pressure is followed by secondary hæmorrhage.

In employing pressure, it must be borne in mind also that, *if applied accurately to the mouth of the bleeding vessel, the actual force required to stop the flow of blood is very small*. In the palmar arch, for instance, less than a quarter of an ounce accurately applied would close the mouth of the artery.

6. **FORCIBLE FLEXION**, as a means of arresting hæmorrhage from the arteries of the limbs, has in recent years been advocated by Heath of Newcastle, Adelman of Dorpat, and others. Its application is founded on the fact, specially pointed out in 1813 by Formey, that flexion of the arm at the elbow-joint weakens or arrests the pulsation at the wrist. Malgaigne, Vidal, Fleury, Fry, and some other Surgeons, have reported cases in which the plan was employed successfully; but until lately the method has attracted little attention. Heath, from a number of experiments made by him in the Newcastle Infirmary, has found that flexion of the arm at the elbow, or of the leg at the knee, diminishes or arrests the pulse in the arteries beyond. In this respect he confirms the observations of Hyrtl and others; but he finds also that in the arm the process is greatly aided by placing a piece of lint or a handkerchief rolled up in the bend of the elbow; and in the lower limb, by bending the thigh on the abdomen at the same time that the leg is bent at the knee. Where flexion acts successfully as a means of hæmostasis, as it is reported to have done in several cases—especially in wounds of the palmar arteries and the vessels of the forearm—it probably does so by weakening the current of blood, so as to favour the closure of the arterial wound in the manner described in speaking of the Natural Arrest of Hæmorrhage. The apparent simplicity and safety (when carefully applied) of flexion render it worthy of further trial in cases of injury of the arteries of the forearm and hand, or of the leg and foot. A roll of lint or other soft material having been placed in the flexure of the joint, the limb should be bent until it is perceived that the hæmorrhage is arrested, and should then be maintained in position by means of a handkerchief or bandage. Care must of course be taken not to exercise too great compression, by which gangrene might be produced. The flexion should be kept up till the Surgeon, by careful examination, is satisfied that there is no further risk of hæmorrhage.

7. **TORSION OF CUT ARTERIES** for the arrest of hæmorrhage is mentioned by Galen; but the practice seems to have been forgotten until about 1828. It was revived in France by Amussat, Velpeau, and Thierry; and in Germany by Fricke, but notwithstanding the efforts made to force it on the attention of Surgeons, it was gradually abandoned, even by its strongest advocates.

Torsion has never come into general use, and has certainly been too much neglected, even in this country, where it has been more commonly adopted than elsewhere. It may be practised in various ways. Amussat recommended that the artery be drawn out for about half an inch with one pair of forceps; that it then be seized close to the tissues with another forceps, and that the end then be twisted off (Fig. 125). This plan was applicable only to the larger arteries, which could be cleanly isolated from the surrounding tissues. Thierry simply seized the artery and twisted it in the direction of its axis, and this plan is undoubtedly most effectual, as the second pair of forceps prevents the inner and middle coats from being properly turned up into the lumen of the vessel. Velpeau and Fricke advised that the end be

Fig. 125.—Torsion of Brachial Artery.

not taken off, but merely twisted, from four to eight times, according to the size of the vessel. The former plan is termed "free torsion," the latter "limited torsion." In seizing the artery it is particularly important, as Dupuytren pointed out, that the whole vessel be grasped by the forceps, and that care be taken not to introduce one blade into the open end of the vessel, and thus twist only half of it. Haemorrhage from the largest vessels may be effectually stopped by torsion. Amussat and Velpeau repeatedly used it to close the femoral, brachial, ulnar, and radial arteries in amputations of the thigh, arm, and forearm; and more recently Cooper Forster and Bryant at Guy's Hospital, and Callender at St. Bartholomew's, have used it successfully as the only means of arresting arterial haemorrhage after operations. Their experience shows that, to say the least, torsion is as safe as any other mode of occluding a wounded artery.

In order to apply torsion successfully, a strong pair of forceps, with accurately fitting serratures, must be used (Fig. 126), and the width of the blades should vary with the size of the artery to be twisted. In applying

torsion to a large vessel, it is better not to twist the end completely off; three or four sharp turns usually suffice, during which the inner and middle coats are felt to give way and all resistance to cease. Smaller vessels may be

Fig. 126.—Torsion-forceps.

twisted till the part included in the forceps comes off. Even with small vessels it will be found that the more cleanly the vessel can be isolated the more certainly will the bleeding be stopped. Torsion is most easily applied to large vessels, which can be accurately seized in the forceps; it is most difficult with small vessels, especially if they are situated in dense structures, or in tissues infiltrated with inflammatory products. Bryant states that degeneration of the inner and middle coats in no way increases the difficulty in securing the artery, fewer turns in fact being required to close a diseased than a healthy vessel.

FIG. 127.—A Femoral Artery from a fresh dead body, twisted freely and laid open. The inner and middle coats are turned up into the lumen of the vessel for half-an-inch.

In torsion an artery is placed in the condition of one that is lacerated or torn through. The inner and middle coats are ruptured immediately above the part seized in the forceps, and are turned upwards into the lumen of the vessel; the external coat is twisted into a kind of screw beyond them (Fig. 127). If a large vessel be treated in this way in the dead body and cut off about half an inch above the twisted part, it can be seen by looking down the lumen of the vessel that the inverted inner and middle coats completely close the vessel in a manner roughly resembling the closed aortic valves. A coagulum forms, adherent at its lower end to the injured coats, and the subsequent changes within the vessel are identical with those already described (p. 414) as occurring in permanent occlusion of a divided artery. The twisted end becomes absorbed after being embedded in the coagulable exudation that unites the surface of the wound in the first few hours, but it

may separate as a slough if exposed to unfavourable conditions, as in an ill-drained wound with decomposing discharges, or on an open surface.

Torsion and Ligature Compared.—The employment of torsion as a substitute for the ligature is advocated on three grounds: 1, that, whilst equally safe, it is more easy of application; 2, that it is less likely to be followed by secondary hæmorrhage; and 3, that when an artery is closed by torsion, no foreign body is left in the wound that could interfere with its direct union.

Let us briefly examine the advantages claimed for torsion over the ligature.

1. As far as ease of application is concerned, there can be no doubt that the advantage is in favour of the ligature. This is very markedly the case with small vessels and those that cannot be drawn out of their sheaths. In the case of the larger arteries, that can be denuded and drawn out of the neigh-

houring tissues, it is at least as easy to ligature the vessel as to twist it efficiently.

2. With reference to the comparative freedom from secondary hæmorrhage, we have few data; but all those Surgeons who have extensively employed torsion agree in stating that it is very rarely followed by secondary hæmorrhage. The same may, however, be said with equal truth of the ligature as used at the present time.

3. The torsion of arteries was strongly advocated on the ground that, whilst quite as safe as the ligature, there would after its employment be less liability to inflammation and suppuration, as no foreign body was left in the wound. This argument was used especially by Amussat; Manec and others maintained that the twisted end, of a large artery at any rate, is in reality a foreign body. At the present day, when the treatment of wounds is so much better understood than it was in their time, these arguments are of but little practical importance. We know that a piece of dead tissue, the size of the twisted end of an artery, becomes speedily buried in the exudation that forms during the first twenty-four hours after the infliction of a wound, provided that the cavity is properly drained, and the surfaces brought accurately together and kept at rest; and that under these circumstances it is readily absorbed without causing inflammation or suppuration. In fact, it acts as an irritating foreign body only when it remains uncovered and undergoes decomposition. The same is true of the ligatures in common use at the present day. On the other hand, the old silk ligature, the ends of which were left hanging out of the wound, infallibly acted as an irritant, and excited suppuration in its track. Torsion, therefore, undoubtedly presents advantages over the old silk ligature, and is equally safe and no more likely to interfere with primary union than an absorbible ligature. The latter possesses, however, the advantage of much greater ease of application, and is therefore preferred by the majority of Surgeons.

4. FORCIPRESSURE is a mode of arresting hæmorrhage which has been recommended as of use in certain cases by Spencer Wells, Koebleré, and Petani. It consists in seizing the end of the vessel in a pair of forceps having strong short blades somewhat deeply serrated, and long scissor handles provided with a catch (Fig. 128). The forceps can be closed with sufficient force to crush the end of the vessel between the blades. The form of forceps represented in the figure is that invented by Spencer Wells, which is certainly the most convenient and efficient. The use of these forceps as a temporary means of arresting hæmorrhage has already been alluded to. When used in this way it will frequently be found that, on relaxing their hold after a few minutes, no bleeding takes place. Under these circumstances, experience shows that the closure of the vessel is as safe as that effected by torsion. Should the Surgeon wish to make the arrest of bleeding still more certain, he may give the forceps a few turns while removing them, and thus apply torsion. Forcipressure is occasionally useful in deep wounds in which a ligature cannot be applied. In these cases, in order to make the closure of the vessel more certain, the forceps may be left in the wound for twelve or twenty-four hours and then carefully removed.

5. LIGATURE is the means to which Surgeons commonly have recourse for the arrest of hæmorrhage from wounded arteries.

The Ligature was undoubtedly employed to a considerable extent by the

later Roman Surgeons, and is frequently mentioned by Celsus. With the decline of Surgery during the dark ages it fell almost completely into disuse, giving way to such barbarous and inefficient means as the employment of the actual cautery, the performance of operations with red-hot knives, or the application of boiling pitch or molten lead to the freshly-cut surface. It seems, however, never to have been altogether abandoned. Almost every surgical writer of any importance from the time of Celsus to the sixteenth century mentions the ligature, and most recommend its use in accidental wounds of large vessels. It was only in amputations that the rule was absolute to use the cautery, and this, as Pare tells us, was "not only to stay the flux of blood, but chiefly to correct the malignity or gangrenous putrefaction which

might spoil the neighbouring parts." To what extent the ligature was used before the sixteenth century it is difficult to determine, but that it was a recognised mode of treatment of hæmorrhage is clear. In 1552 Ambroise Paré, Surgeon to the King of France, first practised the application of the ligature to the divided vessels in amputations, and advocated its use under all possible circumstances as the safest and most painless method of arresting arterial hæmorrhage. But so slowly did the ligature make way, that Sharpe, Surgeon to Guy's Hospital, writing in 1761, two centuries after its re-introduction by Paré, found it necessary, in his well-known work, entitled "A Critical Enquiry into the Present State of Surgery," formally to advocate its employment for the arrest of hæmorrhage from wounded arteries, in preference to styptic or the cautery, on the ground that "it was not as yet universally practised amongst Surgeons residing in the more distant countries of our kingdom." What, it may be asked, was the reason that it took two centuries to promulgate

Fig. 125. — Compression forceps.

the use of this simple and most efficacious means for the arrest of hæmorrhage? The reason simply was, that Surgeons were totally ignorant of the means employed by Nature for the occlusion of arteries; that they consequently did not know how to apply a ligature to these vessels, or what kind of ligature should be used; and that, in their anxiety to avoid the occurrence of secondary hæmorrhage, and to make all safe, they fell into the very errors they would have endeavoured to avoid, had they been acquainted with the nature of the processes by which the closure of the artery and the separation of the ligature are effected.

Between twenty and thirty years after the time at which Sharpe wrote Hunter introduced that great improvement in the surgical treatment of aneurism—the deligation of the artery at a distance from the sac, and in a healthy part of its course; but this great advance in the treatment of aneurism

was but coldly received, and ran some risk of being lost in consequence of the ill-success that attended the earlier operations. In this operation, four ligatures were used, each of which was

applied so slackly as merely to compress the artery, in order to avoid too great a degree of pressure at any one point ; and the artery was denuded, so that a spatula could be passed under it. Although in his subsequent operations Hunter contented himself with employing but one ligature, yet sometimes the vein was included in this ; and he did not draw the noose tight for fear of injuring the coats of the vessel, in accordance with the doctrine of the day—Surgeons generally at this time being haunted by the dread of injuring, and thereby weakening, the coats of the artery ; and, in order to avoid doing so, they adopted modes of treatment that almost infallibly led to ulceration of the vessels and consecutive hæmorrhage. The employment of several ligatures of reserve, applied slack, the use of broad tapes, the interposition of plugs of cork, wood, agaric, or lead, or of rolls of lint or plaster, between the thread and the vessel, were some amongst the plans that were in common use. And how can we be surprised that the patients perished of hæmorrhage, and that

Fig. 129.—End of Artery drawn forwards. Application of Ligature.

ligature of the vessel was nearly as inefficient and fatal a means of arresting bleeding as the use of a cautery, or of a button of white vitriol ?

Jones, by a series of admirably conducted investigations on living animals, showed that the very point which Surgeons were anxious to avoid—the division of the coats of the vessel by the tightening of the noose—was that on which the patient's safety depended ; he also pointed out the form and size of ligature that was most safe, the degree of force with which it should be applied, and the processes adopted by Nature for the occlusion of the vessel. Thus a more rational practice was introduced, and then, for the first time, Surgeons had full confidence in the use of the ligature.

Application of the Ligature.—The mode of application of the ligature varies according as (1) the cut end of the artery has to be tied in an open wound, or as (2) the vessel has to be secured in its continuity.

1. When the **divided vessel in an open wound** has to be tied, as after an amputation, the mouth of the artery must be seized and drawn forwards (Fig. 129). For this purpose a tenaculum, or sharp hook, was formerly used, and answered the purpose very well. There were, however, objections to this

instrument: thus, it occasionally seized other tissues with the artery, and, occasionally, an accidental puncture having been made by it behind the part of the vessel to which the ligature was applied, ulceration and subsequent fatal hæmorrhage ensued, as I have seen in one case. The most convenient instrument for the purpose of drawing forward the artery, and one to which the ligature is usually applied, is Liston's "bull-dog" forceps. These have been described as being specially having the blades expanded just above the points, so that the ligature can be slipped over their end on to an artery, and then drawn back as between bones or close to the interosseous membrane, in a position in which it is sometimes troublesome to tie a vessel by other means.

When applying the forceps, care must be taken that it be put well over the cut artery, and that the points of the forceps, and that it be tied in such a manner, which will not slip (Fig. 131). As the knot is being made, the forefingers should be in close contact with the points of the forceps, and be pressed slightly downwards on the artery, otherwise the artery will be pushed forwards out of its bed, or the forceps pulled off it. In

Fig. 130.—"Bull-dog" Forceps, modified.

Fig. 131.—The Ligature, or reef-knot.

the bleeding point may be so situated, that the ligature is most easily passed round it by means of an ordinary curved needle.

If the artery has to be ligatured **in its continuity** at the injured point, which does not completely divide it, it must be exposed by a longitudinal incision as the state of the parts will admit: the wound being made in such a direction as to do the least possible injury to the surrounding structures.

Whenever, for any reason a Surgeon determine to apply a ligature at a distance from the seat of the disease or injury, he selects that part of the vessel which is best adapted to the operation, and guided by his anatomical knowledge exposes it on the chosen spot. The particular operations by which each of the **arteries** may be exposed and tied will be described in the chapter on the treatment of Special Aneurisms; but the general principles which guide the Surgeon in the application of a ligature to a large artery in its continuity will be given here.

Whenever it is possible, the ligature should be applied at some distance from any branch, in order that the formation of the internal coagulum may not be interfered with, either by the stream of blood leaving the main trunk and passing on the proximal side of the ligature, or by that entering it by means of the collateral circulation on the distal side. When this is impossible, it is better to tie the ligature on the proximal side of the branch, so that a clot may form and protect the injured part of the vessel from the direct flow of blood from the heart. In some cases, especially if

the anastomosing vessels are very abundant, it would be safer to ligature the branch also close to the main trunk.

Other things being equal, that part of the artery is to be chosen which is most superficial, and in relation with the fewest important structures. Thus the point selected in the carotid is above the omo-hyoid, and the superficial femoral is always, when possible, tied in preference to the popliteal.

Having determined the point to which the ligature is to be applied, the operator first makes an incision through the skin and fat to the deep fascia; he then, by careful dissection, exposes the sheath of the vessel, and finally opens the sheath and passes the aneurism needle between it and the external coat.

The first incision is usually made in the course of the vessel; for in most parts of the body the chief nerves, veins, and muscles run in the same line as the main artery. When, however, an incision in the line of the artery would injure important parts, the Surgeon must make an oblique or transverse wound, the direction being determined by the anatomical relations of the part. Thus in ligature of the brachial at the bend of the elbow, the incision is made across the line of the artery, in order to avoid the median basilic vein; and in ligature of the external iliac it is made nearly parallel to Poupart's ligament to facilitate the retraction of the peritoneum in exposing the artery. In making the incision, the Surgeon is guided by some fixed line known as the "*directing or guiding line*." In some cases this corresponds with the anatomical line of the artery, as in the operation for ligature of the anterior tibial; in others it is distinct from this, having reference rather to the structures which have to be turned on one side to expose the vessel. Thus in the operation for ligature of the carotid artery, the directing line for the first incision is the inner edge of the sterno-mastoid, while the line of the artery is from midway between the angle of the jaw and the mastoid process to the sterno-clavicular articulation. Both the anatomical line of the artery and the surgical directing line should be carefully studied and kept in mind.

In making the first incision, the skin should be put on the stretch by the fingers of the left hand. The length of the incision will necessarily vary with the depth of the artery and with the amount of superficial fat; but it must always be sufficient to give the operator a clear view of what he is doing in deeper dissection. If the artery be superficial, or if there be parts of importance in its vicinity, the first incision should not penetrate deeper than the skin. But if the vessel be deeply seated and no parts of importance intervene, it may be carried at once through the subcutaneous areolar tissue, until the fascia is exposed. This must then be pinched up with the forceps, and opened by the edge of the scalpel laid horizontally (Fig. 132, p. 433). Through this opening a grooved director may then be passed, and the fascia incised upon it without risk to subjacent parts; or the fascia may be carefully divided by the method described on p. 44, Fig. 7.

If the vessel be superficial, its sheath will come into view as soon as the deep fascia is divided, and the operator proceeds at once to clean the artery and to pass the ligature; but if it be more deeply seated, the dissection must be continued till the vessel is exposed. In carrying out the deeper dissection, the Surgeon is still guided by definite anatomical points, each of which must be made out in order, and clearly recognised. Malgaigne gave these the name of the "*rallying-points*" of the operation, and laid down the following excellent rule: "The Surgeon should not at once set himself to look for the artery,

instrument; thus, it occasionally seized other tissues with the artery, and, occasionally, an accidental puncture having been made by it behind the part of the vessel to which the ligature was applied, ulceration and subsequent fatal hæmorrhage ensued, as I have seen in one case. The most convenient instrument for the purpose of drawing forward the artery, and one to which no objection whatever applies, is Liston's "bull-dog" forceps. These have been conveniently modified by having the blades expanded just above the point (Fig. 130), so that the ligature can be slipped over their end on to an artery that is deeply seated, as between bones or close to the interosseous membrane of the leg—a situation in which it is sometimes troublesome to tie a vessel by any other means.

In applying the ligature, care must be taken that it be put well over the cut end of the artery, that it clear the points of the forceps, and that it be tied tightly in a reef-knot, which will not slip (Fig. 131). As the knot is tightened, the tips of the forefingers should be in close contact with the points of the forceps, and be pressed slightly downwards on the artery, otherwise the vessel may be dragged forwards out of its bed, or the forceps pulled off it. In

Fig. 130.—Liston's "Bull-dog" Forceps, modified.

Fig. 131.—The Ligature, or reef-knot.

some cases the bleeding point may be so situated, that the ligature is most conveniently passed round it by means of an ordinary curved needle.

2. When the artery has to be ligatured **in its continuity** at the injured spot for a wound which does not completely divide it, it must be exposed by as careful a dissection as the state of the parts will admit: the wound being enlarged, if necessary, in such a direction as to do the least possible injury to surrounding structures.

If for any reason a Surgeon determine to apply a ligature at a distance from the seat of the disease or injury, he selects that part of the vessel which is best adapted to the operation, and guided by his anatomical knowledge exposes it in the chosen spot. The particular operations by which each of the main arteries may be exposed and tied will be described in the chapter on the treatment of Special Aneurisms; but the general principles which guide the Surgeon in the application of a ligature to a large artery in its continuity will be given here.

Whenever it is possible, the ligature should be applied at some distance from any branch, in order that the formation of the internal coagulum may not be interfered with, either by the stream of blood leaving the main trunk immediately on the proximal side of the ligature, or by that entering it by means of the collateral circulation on the distal side. When this is impossible, it is safer to apply the ligature on the proximal side of the branch, so that a clot may be formed above it and protect the injured part of the vessel from the direct impulse of the stream of blood from the heart. In some cases, especially if

the anastomosing vessels are very abundant, it would be safer to ligature the branch also close to the main trunk.

Other things being equal, that part of the artery is to be chosen which is most superficial, and in relation with the fewest important structures. Thus the point selected in the carotid is above the omo-hyoid, and the superficial femoral is always, when possible, tied in preference to the popliteal.

Having determined the point to which the ligature is to be applied, the operator first makes an incision through the skin and fat to the deep fascia; he then, by careful dissection, exposes the sheath of the vessel, and finally opens the sheath and passes the aneurism needle between it and the external coat.

The first incision is usually made in the course of the vessel; for in most parts of the body the chief nerves, veins, and muscles run in the same line as the main artery. When, however, an incision in the line of the artery would injure important parts, the Surgeon must make an oblique or transverse wound, the direction being determined by the anatomical relations of the part. Thus in ligature of the brachial at the bend of the elbow, the incision is made across the line of the artery, in order to avoid the median basilic vein; and in ligature of the external iliac it is made nearly parallel to Poupart's ligament to facilitate the retraction of the peritoneum in exposing the artery. In making the incision, the Surgeon is guided by some fixed line known as the "*directing or guiding line*." In some cases this corresponds with the anatomical line of the artery, as in the operation for ligature of the anterior tibial; in others it is distinct from this, having reference rather to the structures which have to be turned on one side to expose the vessel. Thus in the operation for ligature of the carotid artery, the directing line for the first incision is the inner edge of the sterno-mastoid, while the line of the artery is from midway between the angle of the jaw and the mastoid process to the sterno-clavicular articulation. Both the anatomical line of the artery and the surgical directing line should be carefully studied and kept in mind.

In making the first incision, the skin should be put on the stretch by the fingers of the left hand. The length of the incision will necessarily vary with the depth of the artery and with the amount of superficial fat; but it must always be sufficient to give the operator a clear view of what he is doing in the deeper dissection. If the artery be superficial, or if there be parts of importance in its vicinity, the first incision should not penetrate deeper than the skin. But if the vessel be deeply seated and no parts of importance intervene, it may be carried at once through the subcutaneous areolar tissue, until the fascia is exposed. This must then be pinched up with the forceps, and opened by the edge of the scalpel laid horizontally (Fig. 132, p. 433). Through this opening a grooved director may then be passed, and the fascia incised upon it, without risk to subjacent parts; or the fascia may be carefully divided by the method described on p. 14, Fig. 7.

If the vessel be superficial, its sheath will come into view as soon as the deep fascia is divided, and the operator proceeds at once to clean the artery and to pass the ligature; but if it be more deeply seated, the dissection must be continued till the vessel is exposed. In carrying out the deeper dissection, the Surgeon is still guided by definite anatomical points, each of which must be made out in order, and clearly recognised. Malgaigne gave these the name of the " *rallying-points* " of the operation, and laid down the following excellent rule: "The Surgeon should not at once set himself to look for the artery,

but should seek solely the first rallying-point ; then the second ; then the third, if there is one ; and so on, till he reaches the vessel." Thus in the operation of ligature of the carotid, the first rallying-point is the inner side of the sterno-mastoid, and until that is made clear, nothing else should occupy the operator's mind ; the second point is the upper border of the anterior belly of the omo-hyoid, and it is not till this is found and drawn downwards, that the artery itself need be thought of. During the deeper dissection the wound must be held open with blunt hooks or copper spatulae, and this duty should if possible be entrusted to a single assistant. If two undertake it, one is sure to pull more strongly than the other, and thus disturb the relation of the superficial wound to the deeper parts.

Having reached the sheath, the next step of the operation consists in exposing the artery, and is one of great delicacy. The object of the operator is to open the sheath in such a way that the needle can be passed between it and the external coat, and at the same time to separate the artery from its sheath for as short a distance as possible. Separation of an artery from its sheath cuts off the blood-supply of its coats, as this is derived from the *vasa vasorum* which ramify in the sheath ; if, therefore, the artery be separated extensively, the isolated part will slough. At the same time, it is very important that the artery be really separated cleanly from the sheath, as if this is done a smaller amount of tissue is included in the ligature, and the division of the inner and middle coats is more perfectly effected. Perfect cleaning of the artery, moreover, greatly facilitates the passage of the needle. If we cut an artery through, it retracts within its sheath, leaving that attached to the surrounding parts. This clearly shows that the sheath is more adherent to the surrounding parts than to the external coat, and that the loosest tissue, through which the needle will pass most readily, is that between the sheath and the outer coat. In fact, if the artery be properly cleaned, it is very unlikely that any accident will happen in passing the needle.

It must not be forgotten that some of the larger arteries are enclosed in a sheath derived from the fascia of the part, and it is important not to confound this with the true sheath. Thus, the carotid artery is enclosed in the sheath of cervical fascia common to it, the jugular vein, and the pneumogastric nerve, and in this case the operator will have to open the true sheath of the artery after having exposed it by opening the common sheath. The sheath of an artery may usually be recognised by the small vessels that can be seen ramifying in it, while the external coat is almost white, like the conjunctiva and the sclerotic of the eye respectively. Syme's rule in cleaning an artery, "to dissect down till the 'white coat of the vessel' comes into view," is founded upon this fact.

The sheath is opened by pinching it up with the forceps and applying the knife horizontally (Fig. 132). The point should never be used, nor the blade turned downwards against the artery, as an incautious movement or the mere pulsation of the vessel might cause it to be wounded. If the white coat of the artery does not come into view at once, it will be because the sheath is not completely divided, and the operator must then pinch it up again in exactly the same place, and again cut the areolar tissue seized in the forceps. The appearance of the white external coat, and the exceedingly loose areolar tissue which comes into view, show him when he has completely opened the sheath. He then catches hold of the edge of the opening he has made, and, putting it

outer one. The divided coats are separated for a short distance from the external coat and turned upwards and downwards into the lumen of the vessel.

The first change that takes place after the application of the ligature is the **Formation of the Internal Coagulum.** For the first few hours there is little if any appearance of this; but, within about twenty-four or thirty-six hours after the application of the ligature, a coagulum will usually be found extending some distance from the ligature and adherent by its base to the injured part of the vessel. The part in immediate contact with the divided inner and middle coats will by this time be found to be of a yellowish or buff colour, owing to its being infiltrated or replaced by the inflammatory exudation which has been poured out in the bottom of the *cul-de-sac* formed by the turn-

Fig. 136.—Immediate effects of the Application of a Ligature.

Fig. 137.—Femoral Artery, SIX hours after Amputation.

ing inwards of the divided coats. About the third day the clot (Figs. 137 and 138) will be found to be conical in form, firmer in structure, and more adherent to the inner coat of the artery, and by this time it extends most frequently as far as the nearest branch given off from the vessel above the ligature (Fig. 139). Its base is more distinctly decolorised, the remainder being of a dark purple or maroon colour. Its apex lies loose and floating in the artery.

The further changes that occur within the artery are the same as those already described as taking place in the permanent closure of a divided vessel (p. 415).

In some cases, there is an imperfect formation of the internal coagulum, or even a total absence of it should a branch arise immediately above the ligature. In other cases, the insufficient formation of the coagulum is apparently due to the constitutional condition of the patient. Sometimes the clot seems to undergo a kind of disintegration or liquefaction after it has been formed (Fig. 140). This I have seen happen in a case of ligature of the carotid artery, in which death occurred from visceral disease ten weeks after the operation; and in the femoral, in cases of pyæmia.

When an artery is ligatured in its continuity the coagulum formed in the usual *cul-de-sac* is seldom so abundant as that on the proximal side of the ligature. In other respects the internal changes that occur are identical on the two sides of the ligature.

but should seek solely the first rallying-point ; then the second ; then the third, if there is one ; and so on, till he reaches the vessel." Thus in the operation of ligature of the carotid, the first rallying-point is the inner edge of the sterno-mastoid, and until that is made clear, nothing else should occupy the operator's mind ; the second point is the upper border of the anterior belly of the omo-hyoid, and it is not till this is found and drawn downwards, that the artery itself need be thought of. During the deeper dissection the wound must be held open with blunt hooks or copper spatulae, and this duty should if possible be entrusted to a single assistant. If two undertake it, one is sure to pull more strongly than the other, and thus disturb the relation of the superficial wound to the deeper parts.

Having reached the sheath, the next step of the operation consists in exposing the artery, and is one of great delicacy. The object of the operator is to open the sheath in such a way that the needle can be passed between it and the external coat, and at the same time to separate the artery from its sheath for as short a distance as possible. Separation of an artery from its sheath cuts off the blood-supply of its coats, as this is derived from the *vasa vasorum* which ramify in the sheath ; if, therefore, the artery be separated extensively, the isolated part will slough. At the same time, it is very important that the artery be really separated cleanly from the sheath, as if this is done a smaller amount of tissue is included in the ligature, and the division of the inner and middle coats is more perfectly effected. Perfect cleaning of the artery, moreover, greatly facilitates the passage of the needle. If we cut an artery through, it retracts within its sheath, leaving that attached to the surrounding parts. This clearly shows that the sheath is more adherent to the surrounding parts than to the external coat, and that the loosest tissue, through which the needle will pass most readily, is that between the sheath and the outer coat. In fact, if the artery be properly cleaned, it is very unlikely that any accident will happen in passing the needle.

It must not be forgotten that some of the larger arteries are enclosed in a sheath derived from the fascia of the part, and it is important not to confound this with the true sheath. Thus, the carotid artery is enclosed in the sheath of cervical fascia common to it, the jugular vein, and the pneumogastric nerve, and in this case the operator will have to open the true sheath of the artery after having exposed it by opening the common sheath. The sheath of an artery may usually be recognised by the small vessels that can be seen ramifying in it, while the external coat is almost white, like the conjunctiva and the sclerotic of the eye respectively. Syme's rule in cleaning an artery, "to dissect down till the 'white coat of the vessel' comes into view," is founded upon this fact.

The sheath is opened by pinching it up with the forceps and applying the knife horizontally (Fig. 132). The point should never be used, nor the blade turned downwards against the artery, as an incautious movement or the mere pulsation of the vessel might cause it to be wounded. If the white coat of the artery does not come into view at once, it will be because the sheath is not completely divided, and the operator must then pinch it up again in exactly the same place, and again cut the areolar tissue seized in the forceps. The appearance of the white external coat, and the exceedingly loose areolar tissue which comes into view, show him when he has completely opened the sheath. He then catches hold of the edge of the opening he has made, and, putting it

wounds have diminished the frequency of secondary hæmorrhage in the same proportion as they have diminished pyæmia and other unhealthy processes.

Should the ligature be composed of an irritating material which has to cut its way through the ligatured vessel by ulceration, a localised inflammation with suppuration is kept up in the immediate neighbourhood of the injured part of the artery. As a rule this process is closely limited to the immediate neighbourhood of the ligature; and, by the time the noose ulcerates through the external coat, repair is sufficiently advanced within the vessel to render it capable of withstanding the force of the blood-stream—the firm adhesion of the clot to the inner coat serving under these circumstances the important purpose of breaking the direct impulse of the wave of blood upon the new tissue closing the vessel. There are two sources of danger in connection with the coming away of the ligature: either the sloughing may be too extensive, or the ulceration through the artery may take place before the reparative material within is sufficiently firm. Too extensive sloughing may arise when the artery is tied in its continuity, from the vessel having been separated from its sheath to too great an extent during the dissection required to expose it, and its nutrient vessels consequently being divided in great numbers, so as to deprive that portion of the coats of the vessel of its vascular supply; hence the danger of passing a spatula, director, or the handle of a scalpel under the artery, and also of applying several ligatures or a single wide one. When the artery has been divided, sloughing is most commonly the result of septic processes going on in the wound, especially if the artery have been cut long, so that its free end is bathed in the decomposing discharges. Premature ulceration of the vessel may occur from the use of too thick a ligature, which, by causing greater irritation, hastens the process of separation; from excessive degeneration or inflammatory softening of the artery at the point ligatured; or from unhealthy processes occurring in the wound, especially the pressure of pent-up decomposing discharges. As soon as the ligature has ulcerated through that portion of the artery which is included in its noose, it becomes loosened and separates; frequently being thrown off with the discharges, or becoming detached on the slightest traction. *The period of the separation of the ligature* depends upon the size of the artery and the thickness of its coats and of the ligature itself. From the radial or ulnar arteries, it is usually detached by the eighth day; from the femoral, iliac, or subclavian, about the sixteenth or twentieth day. In some cases the ligature may remain attached for a much longer period, owing to the inclusion within its noose of a bit of fascia, nerve, or muscular substance. In order to hasten the separation in these cases, moderate traction and occasional twisting of the ligature used to be practised.

The Ligature.—The best material to use for tying an artery has been the subject of much experimental inquiry and abundant discussion, and can hardly yet be said to be finally determined. Ligatures may be divided into two chief classes: first, those intended to cut through the artery by a gradual process of ulceration, and then to be removed from the wound; and secondly, those intended to become enclosed in the wound during the process of healing, and either to remain permanently encapsuled or to be absorbed.

1. Until about twenty years ago, when absorbable ligatures were reintro-

duced into practice in connection with the antiseptic treatment of wounds, the vast majority of Surgeons made use of ligatures which were removed from the wound after having cut through the artery by a process of ulceration. The material commonly employed with this object was either "dentist's silk" or compressed whipcord well waxed. The ligature was waxed for three reasons: first, to make it more easy to tie when the operator's hands were slippery with blood; secondly, to prevent the danger of the knot slipping after it had been tied; and thirdly, to render it as far as possible non-absorbent, and thus to prevent its taking up septic matter, and becoming needlessly irritating. In the absence of antiseptic precautions, however, this last object was but imperfectly attained. The ligature always became impregnated with the products of putrefaction, and thus acting like a seton produced a suppurating track in its course. Inflammation and suppuration were thus kept up until the ligature separated and the source of irritation was removed. Thus no true repair could take place outside the ligatured vessel till after the removal of the ligature. In the vast majority of cases, however, the processes of repair going on inside the vessel were sufficient to close it safely; and thus hæmorrhage on the separation of the ligature was of comparatively rare occurrence. As has already been stated, the period at which the process of ulceration through the external coat was completed varied with the size of the artery and the thickness of the ligature. Malgaigne pointed out that the size of the ligature also exercised a marked influence on the time at which it came away; the thicker the ligature the greater the irritation it excited, and the sooner was the process of ulceration through the vessel completed. The finest thread possible, provided it was of sufficient strength, was used, as thereby the danger of premature separation was to a great extent avoided, while at the same time the inner and middle coats were more cleanly divided. In some rare cases, as, for example, when the coats of the artery were softened by inflammation, a thicker ligature was used for fear of cutting through the external coat. If it were intended to remove the ligature, one end was cut short and the other brought out of the wound at the most convenient part. Both ends of the ligature on the main artery in an amputation were left, and knotted together as a distinguishing mark. After the first four days the ligatures on the smaller vessels were gently pulled to see if they were loose. The ligature on the main artery was not touched till after the tenth day in the arm, and the fourteenth in the lower limb.

Ligatures are scarcely ever applied in this way at the present time, but it may, of course, happen to the Surgeon to be placed in circumstances in which prepared absorbable ligatures may not be at his command.

2. *Ligatures which become enclosed in the wound during the process of healing, and remain permanently encapsuled or become absorbed.*

Wire Ligatures have been used with this intention in America. The idea originated with Physick and Levert of Alabama, who performed several experiments with threads of gold, silver, platinum, and lead. They found that with these the arteries of animals could be successfully tied, and that, the material of the ligature being unirritating, no evil from suppuration ensued. When the ends of the ligature were cut off close to the vessel, it was found that the small metallic noose became embedded in a cellular capsule. For some reason this means fell into disuse, until it was revived by Marion Sims. At his suggestion I tried it in several cases of amputation and other surgical

bouring tissues, it is at least as easy to ligature the vessel as to twist it efficiently.

2. With reference to the comparative freedom from secondary hæmorrhage, we have few data; but all those Surgeons who have extensively employed torsion agree in stating that it is very rarely followed by secondary hæmorrhage. The same may, however, be said with equal truth of the ligature as used at the present time.

3. The torsion of arteries was strongly advocated on the ground that, whilst quite as safe as the ligature, there would after its employment be less liability to inflammation and suppuration, as no foreign body was left in the wound. This argument was used especially by Amussat; Manec and others maintained that the twisted end, of a large artery at any rate, is in reality a foreign body. At the present day, when the treatment of wounds is so much better understood than it was in their time, these arguments are of but little practical importance. We know that a piece of dead tissue, the size of the twisted end of an artery, becomes speedily buried in the exudation that forms during the first twenty-four hours after the infliction of a wound, provided that the cavity is properly drained, and the surfaces brought accurately together and kept at rest: and that under these circumstances it is readily absorbed without causing inflammation or suppuration. In fact, it acts as an irritating foreign body only when it remains uncovered and undergoes decomposition. The same is true of the ligatures in common use at the present day. On the other hand, the old silk ligature, the ends of which were left hanging out of the wound, infallibly acted as an irritant, and excited suppuration in its track. Torsion, therefore, undoubtedly presents advantages over the old silk ligature, and is equally safe and no more likely to interfere with primary union than an absorbable ligature. The latter possesses, however, the advantage of much greater ease of application, and is therefore preferred by the majority of Surgeons.

4. FORCIPRESSURE is a mode of arresting hæmorrhage which has been recommended as of use in certain cases by Spencer Wells, Koerberle, and Penn. It consists in seizing the end of the vessel in a pair of forceps having strong short blades somewhat deeply serrated, and long scissor handles provided with a catch (Fig. 128). The forceps can be closed with sufficient force to crush the end of the vessel between the blades. The form of forceps represented in the figure is that invented by Spencer Wells, which is certainly the most convenient and efficient. The use of these forceps as a temporary means of arresting hæmorrhage has already been alluded to. When used in this way it will frequently be found that, on relaxing their hold after a few minutes, no bleeding takes place. Under these circumstances, experience shows that the closure of the vessel is as safe as that effected by torsion. Should the Surgeon wish to make the arrest of bleeding still more certain, he may give the forceps a few turns while removing them, and thus apply torsion. Forcipressure is occasionally useful in deep wounds in which a ligature cannot be applied. In these cases, in order to make the closure of the vessel more certain, the forceps may be left in the wound for twelve or twenty-four hours and then carefully removed.

5. LIGATURE is the means to which Surgeons commonly have recourse for the arrest of hæmorrhage from wounded arteries.

The Ligature was undoubtedly employed to a considerable extent by the

supported by pebbles at a short distance above the bottom, to afford space for water that slowly subsides to accumulate in and keep it from coming into contact with the hanks of gut which are placed loosely in the upper part of the vessel. The process of preparation goes on best in a cool place, and should be continued *for two months at least*; and the gut goes on improving for an unlimited time if retained in the same oil."

Excellent results were obtained with the gut prepared in this way, but the length of time required before it was fit for use formed a serious objection to the process. Lister therefore undertook a series of experiments with various reagents in the hope of finding some equally efficient and more rapid method. Among the substances with which he experimented, chromic acid was found to give the best results; but if this is used alone or too strong, the gut becomes over-prepared and as unabsorbable as a wire ligature. The method of preparation finally adopted was the following: Dissolve one part of chromic acid in 4,000 parts of distilled water, and add to the solution 200 parts of pure carbolic acid or absolute phenol. Place in the solution a quantity of catgut equal in weight to the carbolic acid: the gut must not be in loose hanks, but wound round some solid body to prevent its untwisting while soaking. If too much gut be added, it will be under-prepared and soften in the wound; if too little, there is a danger of its becoming over-prepared and unabsorbable. At the end of forty-eight hours the preparation is complete, and the gut may be removed and dried. Another mode of preparing the gut is as follows: Take five parts by weight of catgut (wound as above on some solid body) and immerse for twelve hours in chromic acid 1 part and distilled water 100 parts; transfer after removing the excess of liquid with a cloth into 100 parts of sulphurous acid (B. P.); in twelve hours take it out and dry it. As soon as it is dry, it is to be placed in a 1 to 5 solution of carbolic acid in oil, and it is then fit for use; or it may be kept dry and put in a 1 in 20 watery solution for a quarter of an hour before it is used.

Max Schede of Hamburg has used catgut prepared with perchloride of mercury with perfectly satisfactory results. The catgut is wound on a glass reel and placed in a 1 per cent. solution of corrosive sublimate. The thinner sorts remain in six hours, the thicker twelve. The catgut is then removed and placed for twelve hours in absolute alcohol, when it is ready for use. It is kept till required in the alcohol.

The fate of a prepared catgut ligature in a wound has been the subject of much discussion. The examination of ligatures applied in animals, and of pieces of gut used as sutures and ligatures in the human subject, has, however, tolerably clearly proved that, provided all goes well, the following changes occur. Within a short time of its application the carbolic acid or other antiseptic it contains diffuses out of it and the catgut then becomes a perfectly non-irritating thread of fibrous tissue, and has no tendency to excite inflammation in its neighbourhood. It may, however, become irritating if, after losing the carbolic acid, it decomposes or becomes soaked in decomposing discharges. In this state it presents no advantage over an ordinary silk or hemp ligature, in fact it is less safe, as by its premature softening it may leave the external wound before repair has sufficiently advanced internally. If, however, by the antiseptic treatment, it becomes buried in granulation-tissue developed in the process of repair of

and. In properly prepared catgut the absorption proceeds solely from the face, the ligature swelling and softening but little. If such a ligature remained when partially absorbed, it will be found that the surface has a smooth outline, being eaten out into hollows, which are filled with having the appearance of leucocytes. Occasionally a few larger, many-nucleated cells are met with. In an imperfectly prepared ligature the cells are seen penetrating deeply into the substance of the gut between the fibres of fibrous tissue. Fig. 141 represents the surface of a piece of carbolised catgut $\frac{1}{16}$ -in. in thickness, used as a deep stitch in a wound treated antiseptically, and healed by the first intention. It was removed at the end of six days, and was still tough and strong, being only superficially eroded, about one-fifteenth of its thickness having disappeared. The gut prepared by the old process, without chromic acid, and had been in carbolic solution about three years. A portion of the same hank had been successfully employed to ligature the femoral artery in a case of popliteal aneurism.

Usually, as has been shown by Lister, the ligature completely disappears, a coating of new fibrous tissue being deposited round the vessel in its place, the artery is not cut through, the continuity of the external coating uninterrupted. The inner middle coats are as a rule cut through in the application of the ligature, but should it be thought advisable to do this, as in the case of some of the larger arteries, it can be accomplished by using the thickest obtainable, and employing less force in application.

The use of the catgut ligature has, however, been limited to wounds

prepared antiseptically, and good results have been obtained in cases treated by these methods. In these cases the fate of the ligature is less certain. If it is buried in the coagulable exudation which unites the surfaces of a well-prepared and perfectly rested wound in the first few hours, it is protected from absorption, and then follows the course above described. If it should be exposed to septic discharges it softens rapidly, and the knot is usually washed off like a small slough, or the ligature may break up and disappear altogether.

The changes that occur within the artery after the application of a catgut ligature do not differ, so far as is known, from those following any other mode of securing arterial hæmorrhage.

The use of the catgut ligature has not been altogether unattended with accidents. These have been due in most cases to *premature softening of the knot*. The premature softening is due to imperfect preparation. The older method of preparing carbolised catgut occupied at least two months, and even then it was occasionally under-prepared. This has been less frequent since the employment of the new form of catgut prepared by means of chromic acid. The slipping of the knot is sometimes due to the gut being too rigid to tie closely; such gut should never

Fig. 141. Absorption of catgut ligature six days in an aseptic wound. Surface of catgut is splitting up. Leucocytes cover it and wander into the fissures. *L*, leucocytes; *c*, catgut fibres.

be used. Well-prepared gut will tie as closely as silk of the same thickness. When applied to an artery in its continuity, the catgut ligature has in some cases failed to obliterate the vessel. Thus, in a case under the care of Christopher Heath, at University College Hospital, the femoral became pervious shortly after the operation, necessitating the application of a second ligature at a lower point. In a case recorded by T. Smith, of St. Bartholomew's Hospital, not only did the ligature fail to obliterate the artery, but a traumatic aneurism formed at the point at which it had been applied. McCarty has also recorded a case in which the artery became pervious shortly after the operation. In these cases the ligature failed to accomplish the purpose for which it was applied. It is most probable that in all it was due to premature softening of the gut. Treves also has recorded a case in which after 108 days the carotid artery was found to be patent but narrowed at the seat of ligature by a kind of perforated diaphragm. In a case at University College Hospital, in which the right carotid was tied below the omohyoid for an aneurism opposite the larynx, the vessel, when the man died of an aortic aneurism one year after, was found to be obliterated from the aneurism to the innominate. Its coats were continuous, the seat of ligature being recognisable only by some cicatricial tissue adherent to the external coat. It seems possible, therefore, that as the continuity of the external coat is not destroyed, restoration of the lumen of the vessel may take place occasionally even after occlusion lasting a considerable time. In the vast majority of cases, however, in which the catgut ligature has been employed, the vessel has been permanently and safely obliterated.

Carbolised Silk.—The slight degree of uncertainty that has attended the use of catgut, the occasional premature disappearance of the ligature and restoration of the lumen of the vessel, have led some Surgeons to employ fine silk, that known as "Chinese twist" being the best. Silk being an animal substance, and from its softness being unlikely to irritate mechanically, there seems no reason why, if it can be prevented from becoming impregnated with the irritating products of putrefaction, it should not lie harmlessly amongst the tissues, and finally become absorbed or encapsuled. That such has been the case has been abundantly proved by the experience derived from those cases of ovariectomy in which the pedicle has been secured with silk and returned into the cavity of the abdomen. In order that silk may be used with safety and certainty, it must in the first place be rendered aseptic. This is most efficiently done by boiling it for some time in water, and afterwards placing it for twenty-four hours in a 1 in 20 solution of carbolic acid, or in a 1 in 500 solution of corrosive sublimate. It must on no account be waxed, as this makes it incapable of being absorbed. A silk ligature thus prepared will in the great majority of cases give rise to no irritation or suppuration in its neighbourhood. If, however, it should from any cause become exposed to decomposing matter, it will absorb the products of putrefaction, and will then be cast off and discharged from the wound by suppuration.

The fate of a silk ligature when left amongst the living tissues has been experimentally investigated by Lister, Spiegelberg and Waldeyer, Tillmanns, and others. Lister found an aseptic silk ligature applied to the carotid of a dog unchanged at the end of six weeks and embedded in firm fibrous tissue. When he applied a similar ligature to the external iliac artery in a human subject, when he had the opportunity of examining the parts

one year after, he found the greater part of the ligature absorbed, but a small abscess had formed around the knot. Clutton has recorded a case in which the noose of the ligature was discharged from an abscess six weeks after ligation of the external iliac. Boyd had the opportunity of examining a similar ligature applied to the carotid thirty-five days before death, the wound having healed by first intention. The silk was found perfectly unchanged, surrounded by a mass of small round cells with some giant-cells. In another case, recorded by Horsley, a silk ligature was found unchanged after seven weeks. The connective tissue formed a strong fibrous capsule round it, but presented here and there signs of chronic inflammation. The results of experiments on animals by Spiegelberg and Waldeyer, and Tillmanns, agree in every respect with those just mentioned.

It appears, therefore, that a silk ligature may, with proper antiseptic precautions, be safely applied and left in the wound, with a good prospect of its being encapsuled in fibrous tissue and ultimately absorbed.

Tendon Ligatures.—Long tendons dried and afterwards carbolised have also been used as ligatures. Girdlestone of Melbourne has successfully made use of the long tendons from the tail of the kangaroo. These form excellent and most reliable ligatures, and their use has been especially advocated by Dent and Delépine; they are uniform in structure, and undergo absorption very slowly.

Ligature of Arteries without Dividing the Inner and Middle Coats.—In the application of the catgut or silk ligature, it is the object of the Surgeon, as before stated, to tie sufficiently tightly to cut through the inner and middle coats of the artery, and by the compression of the outer coat to turn their divided edges upwards and downwards into the lumen of the vessel. Alexander Monro, B. Bell, Scarpa, and many other Surgeons at the end of the last century and the beginning of this, advocated a more gentle application of the ligature, so as merely to compress the coats to the degree necessary to obstruct the flow of blood, under the impression that the patient's safety was increased by doing less damage to the artery. The observations of Jones, and the experience of all Surgeons, however, proved almost beyond a doubt that if the ligature was to cut through the artery and come away, the safety of the patient depended chiefly on the employment of the finest possible ligatures, tightly tied, so as to cut the inner and middle coats cleanly and completely, and turn them up into the lumen of the vessel in such a way as to plug it almost as thoroughly as in torsion. Broad ligatures loosely tied excited much suppuration round the artery, cut through quickly, and were frequently followed by secondary hæmorrhage. The idea, however, that a vessel can be safely tied without injuring its coats was revived in connection with the absorbable ligatures now in use. Lister at first suggested that the catgut ligature might be applied in this way, but experience seemed to show that its early absorption rendered the obliteration of the vessel uncertain unless the inner and middle coats were cut. R. Barwell has, however, introduced a variety of ligature prepared from the middle coat of the aorta of the ox, which he has successfully applied in a considerable number of cases without injuring the coats of the artery. The **Ox-aorta Ligature** is prepared by separating the outer coat and cutting the middle coat spirally into a long ribbon. This is stretched, by hanging to it a weight of from one to three pounds, according to the breadth of the ligature, and allowed to dry. Ten minutes before being

used it must be soaked in a 1 in 20 solution of carbolic acid in a breadth of the ligature makes it impossible to divide the inner coats of the artery while tying it, and it seems to be more slowly absorbed than catgut. In 1881 Barwell reported fourteen cases in which catgut ligature had been successfully applied to large arteries. In every case obliteration of the vessel was accomplished and nothing was left of the ligature after the operation.

The subject has been brought forward again by C. A. B. W. Edmunds, who, by a series of carefully conducted experiments, has shown that in horses and sheep large vessels can be successfully obliterated by the division of any of their coats by the application of a small round catgut or tendon ligature tied so as merely to arrest the flow of blood. Such a ligature will resist absorption for at least three weeks (a longer period than catgut), and by that time the artery, in all their experiments, was safely obliterated. The mere pressure of the ligature is sufficient to cause proliferation of the endothelium, and union of the surfaces together, thus occluding the vessel. They therefore maintain that if a ligature of an artery in its continuity, it is neither necessary nor dangerous to divide the coats. The probability is that in all arteries of the superficial femoral, and below it, it matters little, as far as is concerned, whether the coats are divided or not, provided the wound takes an aseptic course and unites by first intention, and probably permanent union will be more certain if the inner and middle coat are cut. In large arteries, however, secondary hæmorrhage has occurred with great frequency after catgut ligature with division of the coats, and in some, such as the first subclavian, the innominate, and the aorta, with such constancy that the hope of success seems to lie in not injuring the arterial wall.

Temporary Ligatures.—With the view of removing the inconveniences that resulted from the presence of the ligatures in the arteries, especially with the object of promoting union by the first intention, Surgeons attempted the use of temporary ligatures.

This subject has now in a great measure become a matter of study of which the writings of Jones, Travers, Velpeau, and others are referred to. It may, however, be stated, that the general results of the experiments made and the experience gained on this subject is as follows.

Jones found that, on cutting through the internal and external carotid artery of a horse at three or four different points, with a pair of scissors, and then *immediately* removing them, an "effusion of blood" took place, by which the artery was plugged up." These observations were confirmed by other experimenters, such as Hodgson, Travers, and others. Travers found that, if the ligature was left in for several days, and then removed, obliteration of the artery ensued. He applied a ligature to the femoral artery for popliteal aneurism, and after 24 hours, found the artery closed; and Travers ligatured the artery of a man, and, on removing the ligature at the end of a week, obtained an equally successful result. Their example was followed by Velpeau and Paletta. Notwithstanding these favourable results, the method in the hands of Astley Cooper, Hutchinson, and others, has not been generally adopted. The observation of Vacca that, if the ligature was left in long enough to cause its obliteration, the section of the vessel

or later, caused the use of the temporary ligature to be discontinued in surgical practice even by those who had at one time most strongly advocated it.

10. ACUPRESSURE.—By Acupressure is meant the occlusion of an artery by the pressure of a needle in such a way as to arrest the circulation through it or the hæmorrhage from it. This method of treatment was introduced into surgical practice by the late Sir James Simpson as a substitute for the ligature. Acupressure may be applied in several different ways; but there are four principal methods.

The *first method* is explained by Figs. 142 and 143. The needle is passed

Fig. 142. - Acupressure. First Method.
Raw Surface.

Fig. 143. - Acupressure. First Method.
Cutaneous Surface.

through the cutaneous surface of the flap until its point projects on the raw surface, a little to one side of and above the orifice of the bleeding artery. The latter is then bridged over and compressed by the needle, which re-enters the surface of the wound on the other side of the vessel, and again passes outwards through the skin.

The degree of pressure required effectually to close an artery is certainly much less than Surgeons generally imagine; and in the above proceeding it can be regulated by the acuteness of the angle at which the needle is introduced and again passed out—the cutaneous and other structures of the flap serving as the resisting medium against which the needle compresses the arterial tube.

The *second method* of acupressure consists in taking a short sewing needle

Fig. 144. - Acupressure. Second Method.

Fig. 145. - Acupressure. Third Method.

with a piece of twisted iron wire attached, for the purpose of withdrawing it when necessary. This is dipped down into the soft tissues on one side of the artery; then bridged over the vessel; then dipped down again into the soft structures on the other side of the vessel (Fig. 144). In doing this care must be taken to press the end of the needle down upon the bleeding trunk or tube of the artery with sufficient force.

The *third method* consists in compressing the artery between the needle passed below it and a loop of fine iron wire passed over it. The needle is

passed as in the last cases, but on the opposite side of the artery. The loop of iron wire is thrown over the point of the needle: it is then passed across the artery, drawn tight so as to compress the vessel, and secured by a full twist round the eye end of the needle (Fig. 145). In order to remove the apparatus, all the Surgeon has to do is to pull the twisted wire with which the needle is threaded; thus, in withdrawing the needle, liberates the loop, which may then easily be removed.

The *fourth method* consists in dipping the needle into the tissues close to the artery, then making a turn with the point, and pushing this into the soft part beyond, so as to fix it there, and thus to compress the artery (Fig. 146).

Fig. 146. - Acupressure. Fourth Method.

The *Condition of the Artery* after having been subjected to acupressure has been determined both by experiments on animals and by observations on the human subject. It has thus been ascertained that the pressure of the needle is never sufficient to divide the internal and middle coats.

Occlusion of the artery is effected first by the formation of an adherent clot within the vessel between the point compressed and the nearest collateral branch. The orifice is at the same time sealed by the plastic exudation uniting the surfaces of the wound. It has been shown that in arteries tied without injury to their coats, proliferation of the endothelium takes place in the neighbourhood of the ligature, the new cells growing into the adherent clot, and no doubt the same process occurs after closure of a vessel by acupressure.

The time during which the needle should be left in will vary, according to the size of the artery, from thirty to sixty hours. The needle must not be left in too long, lest irritation be set up and ulceration induced along its track.

At the time that acupressure was introduced hæmorrhage was almost exclusively arrested by silk or hemp ligatures which necessarily formed a barrier to complete union by the first intention. By the early removal of the acupressure pins and wires it was hoped that the wound, being freed from all foreign bodies, would heal without suppuration, and in many cases this result was obtained; but the introduction of the antiseptic treatment and the use of absorbable ligatures brought about the desired result in a much simpler and more certain manner, and acupressure never came into general use. Sufficient experience was obtained, however, to show that even large vessels may be safely obliterated by these means, and circumstances may occasionally arise in which a knowledge of them will be of use to the Surgeon.

COLLATERAL CIRCULATION.—When the main artery of a limb has been ligatured, or in any other way occluded, it is only the direct flow of blood that is interrupted: the indirect supply which is conveyed into the part, by the free communication between the anastomosing vessels of the different portions of the arterial system, is sufficient to preserve its vitality and to prevent occurrence of gangrene. So free are the inoculations between different parts of the arterial system, that, after the largest arteries in the body, smother subcutaneous, the iliac, and even the abdominal aorta, have been ligatured, but blood to support life is at once conveyed into the parts supplied by

This **collateral circulation** is most active in early life, when the

vessels are pliant and elastic, readily accommodating themselves to the increased quantity of blood that they are required to convey. As age advances, the vascular system becomes less elastic, and there is a greater difficulty in the establishment of the collateral circulation. The anastomosing vessels which serve this purpose are invariably furnished by arteries contiguous to that which is ligatured, and come off from the same side of the body. Thus, for instance, after ligature of the superficial femoral, it is by the profunda artery that the supply of blood is carried to the lower extremity. Thus also, when the common carotid is ligatured, the circulation to the parts it supplies is not maintained through the medium of the opposite carotid, although the anastomosis between the ultimate branches of the two vessels are so free upon the throat, and the face, and within the cranium; but it is by means of the inferior thyroid and vertebral arteries (branches of the subclavian on the same side), which become greatly enlarged, that the supply of blood is kept up to the parts on the outside as well as in the inside of the cranium.

The supply of blood that is sent to a limb, after deligation of the main trunk, is at first but small in quantity; being merely sufficient for the maintenance of its vitality, but not enough for the continuance of the usual function of the part. Hence, although the life of a limb may be preserved after the ligature of its artery, it becomes cold, and the patient is often unable to move it for some time, the muscles appearing to be completely paralysed; in a few hours, however, the supply of blood increases, until it reaches its usual standard, when the normal vigour of the part returns. By the end of twenty-four hours the limb will be found to be redder than natural, and the temperature often rises one or two degrees beyond that of the opposite limb, whilst a great sensation of heat is experienced in it by the patient. This period of increased heat may last a week or more.

The re-establishment of the blood-supply to the limb after obliteration of the main trunk is accomplished chiefly by changes taking place in the *Anastomosing Arteries*. Almost immediately after the ligature is tightened they become dilated to their extreme capacity. This is due in a very slight degree to the increased tension caused by the sudden obliteration of the main trunk, for that is equally felt throughout the whole body, except the part supplied by the ligatured artery. It is chiefly the result of relaxation of the muscular coat. This relaxation is probably a reflex phenomenon consequent upon the want of blood in the parts beyond the point of obliteration of the artery. We have already seen that a similar dilatation of the vessels occurs when a limb has been rendered bloodless for a short time by an Esmarch's bandage. The dilatation is not limited to the anastomosing vessels which are directly concerned in carrying the blood from above to below the ligature, but affects the whole arterial system of the limb. It is this that causes the increased redness a few hours after the ligature has been applied. The resistance to the flow of blood is necessarily reduced to the smallest possible degree by this general vascular dilatation, and this to some extent compensates for the increased resistance which necessarily results from the blood having to be driven through a number of small anastomosing arteries, instead of through a single main trunk. The preliminary dilatation is followed by a permanent enlargement of the anastomosing arteries, which increase both in diameter and in length, and thus assume a tortuous or waved form.

Thus in a case of spontaneous obliteration of the first part of the axillary

artery, met with in the dissecting-room of University College, a tortuous vessel, about the size of a crow-quill, and measuring, when straightened out, nine inches in length, was found passing from the internal mammary in the third intercostal space to the external mammary branch of the axillary. Occasionally a number of such arteries may form an interlacement. The anastomosing arteries that carry on the circulation are, as a rule, easily dissected out in a well-injected subject in the dissecting-room, and at one time it was supposed that it was not safe to tie a large artery except in those situations in which such easily demonstrable anastomoses exist. Thus, for instance, after the ligation of the common carotid, the supply of blood is ultimately conveyed by the anastomulations between the superior and inferior thyroid arteries and by the vertebral. When the subclavian is tied the circula-

Fig. 147.—Anatomizing Circulation in Scapular and Pectoralis of Dog, three months after Ligation of Femoral. (After Porta.)

Fig. 148.—Direct Anastomosing Vessels of Right Carotid of Goat, five months after Ligation. (After Porta.)

Fig. 149.—Change in the Vein after Ligation with Anastomosing Vessels.

lation of the upper extremity is carried on by the anastomosis of the posterior scapular and suprascapular from the thyroid axis, with the acromio-thoracic and subscapular of the axillary, of the branches of the internal mammary and intercostal arteries with the external mammary of the axillary, and of the superior intercostal of the subclavian with the superior thoracic of the axillary; and when the external iliac is tied, the blood is conveyed to the lower limb by the anastomulations between the internal mammary and lumbar arteries and the epigastric and circumflex ilii, and by those between the obturator, gluteal, and sciatic arteries, and the circumflex branches of the profunda femoris.

It has, however, repeatedly been shown that the ordinary muscular and subcutaneous vessels of the part are amply sufficient to carry on the circulation, even when no anastomosing arteries can be demonstrated by dissection.

cial vessels ultimately destined to take the place of that which has been lost, the general vascular dilatation of the limb subsides, and circulation is practically restored to its normal condition. During the contraction of the vessels, much pain is often experienced, owing to the pressure of the dilated vessels upon neighbouring nerves.

It is pointed out the curious circumstance that, occasionally when two large branches approach one another, they split, before anastomosing, into three ramusculi, which by uniting form a circle of anastomoses. This is a kind of collateral circulation, Maunoir, Porta, and Stilling have described vessels running directly between the extremities of the obliterated artery, forming species of arterial shoots, springing from the stump of the artery (147).

What takes place in the Trunk.—As a rule it is completely restored above and below the point to which the ligature has been applied to the next important collateral branch (Figs. 148, 149). Beyond this, on the distal side, it is pervious and receives the blood poured into it through the anastomosing channels. Porta and Stilling have shown that, after a small tortuous central canal uniting the two parts of the vessel is formed, a small patent, may be developed down the centre of the fibrous cord of the obliterated portion of the artery.

In which an absorbable ligature has been used and in which consequently the external coat has not been divided, complete restoration of the vessel seems to be an occasional occurrence (see p. 442).

Collateral circulation is occasionally not sufficiently free to preserve the parts supplied by it; as a consequence of this, gangrene results, the parts may become weak or atrophied. This condition may be met with, however, from calcification and rigidity of the arterial system; or it may be the result of an extensive transverse wound of the limb dividing the anastomosing vessels. Copious hæmorrhage by weakening the action of the heart may render it unable to overcome the increased resistance to the collateral circulation through which the blood has to pass, and the circulation may be arrested and gangrene follow. It more rarely happens that we find too great freedom of the anastomoses, so as to lead to a failure of the purposes for which the ligature has been applied, by the rapid passage of blood into the distal side of the vessel, thus perhaps occasioning hæmorrhage.

OF TREATMENT OF PRIMARY ARTERIAL HÆMORRHAGE.—The principles of treatment of wounded arteries are the same whether the artery is treated by ligature, torsion, or acupressure. Having invariably used ligature myself, I have here spoken of tying only, but the reader must understand that the same principles apply to all other means of arresting hæmorrhage.

The principles of the treatment of primary hæmorrhage from wounded arteries are comprised in three great principles: 1. "That no operation ought to be performed on a wounded artery unless it bleeds" (Guthrie); 2. To expose the artery by bleeding, at the wounded part, and to tie it there; and 3. To tie the artery at both ends, if it be completely divided, or to the distal as well as the proximal side of the wound, if it be merely punctured.

These principles of treatment were distinctly laid down by John Bell; but, it is a great Surgeon inculcated these rules of practice with great force,

Surgeons appear to have been led away by the erroneous idea of applying the Hunterian principles in the treatment of aneurism of that of wounded arteries, until Guthrie, by his practice and precepts, and by bringing an overwhelming mass of proof to bear on this important question, recalled the attention of the Profession to the proper and rational treatment of wounded arteries.

1. That no operation ought to be performed on a wounded artery unless it bleeds.—If by the time the Surgeon sees the patient, bleeding has ceased, however furious it may have been, and however probable it may appear from the situation of the wound that a large artery has been injured, no operation should be undertaken. The patient should be placed in bed, the wound should be dressed and a tourniquet applied loosely round the limb ready to be tightened at once should the bleeding again occur. He should be constantly watched by some competent person for the next twenty-four or forty-eight hours. If, before the Surgeon sees the case, bleeding supposed to come from a large vessel has been arrested by pressure, he should at once remove all pressure and remove the pads, as it is not safe to trust to compression for the arrest of hæmorrhage from a vessel of any magnitude. If, on doing this, bleeding occurs, he must be guided in his treatment by the two following rules. If no hæmorrhage appears, he must follow the directions just given. The reason for this rule is that a small artery, especially when wounded near its parent trunk, may for a time pour forth such an amount of blood as to make it appear as if the main trunk itself was implicated, and yet may safely be closed by the processes of natural arrest already described. A man was brought to the University College Hospital with a deep stab in the groin directly in the course of the external iliac artery; a very large quantity of arterial blood had been lost, but the hæmorrhage was arrested on his admission by the application of pressure, &c. From the great and sudden loss of blood it was supposed that the external iliac had been punctured, but it was not thought advisable to perform any operation unless hæmorrhage recurred. The bleeding did not return, and the wound healed without any further trouble.

This rule, as will subsequently be shown, does *not* apply to secondary hæmorrhage, nor to bleeding from vessels opened by ulceration or elongation.

2. To expose the vessel at the wounded part and to tie it there.

—The principal reason for this rule is, that a ligature of the main trunk of an artery at a distance above the wound stops only the direct supply of blood to the limb but does not interfere with the indirect or anastomosing circulation, by which means the blood readily passes into that portion of the vessel which is beyond the ligature, and may, if the anastomosis be very free, continue to escape from the divided artery. Thus, though bright arterial blood may no longer issue from the wound, a continuous stream of the same colour, or of a darker tint, it has become partially deoxygenated in its passage through the anastomosing channels, will continue to well out. This may come from the proximal or the distal end, or from both, but most commonly from the distal end only. If the anastomosis is less free, ligature at a distance on the proximal side will temporarily arrest the hæmorrhage by the formation of a clot at the seat of it

but as the anastomosing circulation becomes fully established and the pressure increases, the clot is forced out and hæmorrhage recommences. A Surgeon endeavours to arrest the flow of blood from a wound of an artery near the palm by a ligature applied to the brachial in the middle

of the arm, and, when the blood bursts forth as furiously as ever, applies successive ligatures to the arteries of the forearm with as little success, he will at last, on account of the continual recurrence of hæmorrhage, be forced to adopt the simple expedient that ought to have been had recourse to in the first instance, namely, that of ligaturing the vessel at the point wounded.

Another reason for the practice now advocated is, that in some cases the Surgeon cannot possibly know what artery is injured unless he seek for it in the wound itself. A large artery may, from the direction of the stab and the impetuous flow of blood that has followed it, appear to be wounded, when in reality it is only a minor branch that has been injured. Thus, for instance, in hæmorrhage from a stab in the axilla, which proved fatal notwithstanding the ligature of the subclavian artery for supposed wound of the axillary, the long thoracic was found to be the vessel divided; so, also, the external iliac artery has been ligatured for supposed wound of the common femoral, when in reality it was the external pudic that was injured.

Lastly, when the main artery of a limb is wounded, if ligature of the trunk in its continuity on the proximal side of the wound should by any chance succeed in arresting the bleeding, the vessel is obliterated at two points—at the seat of ligature and at the wound—and, consequently, gangrene is very likely to occur as the blood may have to pass through two sets of anastomosing vessels to reach the parts below the wound.

This rule applies to every case in which it is possible to expose the wounded vessel sufficiently to apply a ligature to it. The only exceptions are wounds of certain of the deep branches of the carotid and some cases of wound of the deep palmar arch (see Chapter XVI). As will be seen hereafter it applies to secondary as well as to primary hæmorrhage.

3. The third great principle in the treatment of wounded arteries is, that **a ligature is to be applied to both ends of the vessel, if it be completely cut across; or on both sides of the aperture in it, if it be only partially divided.**

The reason for this rule of practice is founded on physiological grounds as well as on practical experience. If the anastomoses of the part be very free, as in the arteries of the palm or forearm, bleeding may continue from the distal end, uninterrupted by the ligature on the proximal side of the wound; if they be less free, a stream of dark-looking venous blood will probably issue in the course of two or three days. After the collateral circulation has been sufficiently established, bright scarlet blood will burst forth from the distal aperture. Experience has shown that it is in this way that secondary hæmorrhage from wounded arteries commonly occurs, the bleeding coming from the distal and not from the proximal end of the vessel.

In some cases the distal end is so retracted and covered in by surrounding parts, that it cannot be found in order to be ligatured. In these circumstances, if it is not actually bleeding, it may be left alone in the hope that hæmorrhage will not occur. If, however, it be bleeding, a graduated compress must be applied, but such means should never be resorted to until the wound has been freely enlarged and a thorough search made for the vessel. If an arterial branch happen to be divided so close to its origin that it cannot be secured, the case must be treated as one of puncture of the main trunk, which must be ligatured above and below the bleeding orifice.

Mode of Operating.—In order to arrest the hæmorrhage during the

ARREST OF ARTERIAL HÆMORRHAGE.

A screw tourniquet should be applied if the wounded vessel is in need of exposure. A screw tourniquet will usually be found most convenient, as it may be relaxed in order to guide the Surgeon to the wound when the vessel is exposed, and again tightened with little loss of time. It is more effectual and safer than digital compression by an Assistant. It will often be found a great assistance to the Surgeon if the limb be rendered bloodless by Esmarch's bandage before commencing the operation. While this is being done the hæmorrhage must be arrested by digital compression at the most convenient point above the wound. When the wound is in such a situation that a tourniquet cannot be applied, digital compression by an assistant must necessarily be relied on. Hæmorrhage having been temporarily arrested by one of the above means, a large probe should be passed to the bottom of the wound; and, taking this as the centre, a free incision should be made in such a direction as will best lay open the cavity with the least injury to the muscles and other soft parts. After turning out any coagula contained in the wound, and clearing it as well as possible, the injured vessel must be sought for. The situation of this may sometimes be ascertained at once by the gaping of the cut in its coats; but, in many cases, it is necessary to relax the pressure upon the artery, so as to allow a jet of blood to escape, and thus indicate the position of the aperture. If the vessel be only partially divided it must be cleaned in the way already described when treating of ligatures of arteries in their continuity, and a ligature passed by means of an aneurismal needle above and below the wound. When these are tied it is safer to divide the vessel completely at the site of the wound. If the vessel has been completely cut across, each end must be found and drawn forward with the artery forceps and tied as in an open wound. This operation is not always so easy in practice as it seems in description. The artery, if completely divided, retracts considerably, and it is often difficult to find the ends in the midst of the areolar tissue infiltrated and stained with blood. Under these circumstances a portion of the sheath thickened by adherent coagulum may be mistaken for the artery. The proximal end is most commonly found with little difficulty by allowing a jet of blood to escape from it. The distal end may not be bleeding at the time of the operation, though blood would probably escape from it as soon as the anastomosing circulation became established. It can then only be found by a careful search guided by accurate anatomical knowledge.

The artery is usually reached most easily by enlarging the original wound in the parts superficial to it, but Guthrie advises that, in those cases in which the wound passes indirectly to the principal artery from the back or outside of the limb, the Surgeon instead of following the track of the wound, shall cut down on the vessel where it lies nearest the surface; then, on passing a probe through the wound, the spot at which the artery has probably been injured will be pointed out, and the ligature must then be applied in the way usual in cases of primary hæmorrhage.

ACCIDENTS AFTER ARTERIAL OCCLUSION BY SURGICAL MEANS.

It

hat may follow the arrest of primary hæmorrhage from a
are Intermediate or Reactionary Hæmorrhage, Secondary
rhage, and Gangrene of the limb.

IMMEDIATE OR REACTIONARY HÆMORRHAGE.—This term is limited to hæmorrhage occurring within twenty-four hours of the wound of the vessel. It commonly occurs within twelve hours of the infliction of the injury.

Causes.—At the end of an operation the patient is often faint from the shock, loss of blood, and the depressing influence of the anæsthetic : at the same time the exposure of the wound to the air, and the mechanical action of the knife and the sponges, have caused the greatest possible degree of contraction of the mouths of the wounded vessels. Under these circumstances vessels of considerable size may not yield a drop of blood. As soon as the wound is closed, however, and warmly dressed, and the patient put to bed, the shock begins to pass off, the heart beats more forcibly, the contracted vessels dilate, and hæmorrhage takes place. At the same time, if any vessel was imperfectly tied—owing to carelessness on the part of the Surgeon, or the use of badly-prepared rigid catgut—the knot may yield, and the vessel may slip off.

A wound of a collateral branch above the point of application of the ligature, though it does not bleed much at the time, will, as I have seen, cause bleeding as the collateral circulation becomes established.

Phænomena.—As the bleeding comes as a rule only from the smaller vessels, it is seldom very profuse. It usually distends the wound, tightening the ligatures, and causing the patient considerable pain.

Treatment.—Stimulants should be avoided as far as possible during the first twenty-four hours after an operation, so that recovery from shock may be gradual. The treatment is the same as that of primary hæmorrhage. If the oozing is slight, the part may be raised and gentle pressure applied ; if more profuse, the wound must be opened up, and the bleeding vessel secured. If the wound is much distended by clots, the pressure thus produced may arrest the bleeding ; but it is better for the patient under these circumstances to open the wound, turn out the clots, and secure any vessel that may be bleeding. The mass of coagulum between the surfaces would form a serious obstacle to union by the first intention.

After an operation the patient be very faint, and the smaller arteries which are expected to bleed cannot be found, they may sometimes be made to bleed by bathing the wound with carbolic lotion or some other antiseptic at a temperature of about 98° Fahr. In private practice it is better to perform operations if possible early in the morning, so that if reactionary hæmorrhage should occur, it may take place in the day and not in the night.

PRIMARY OR RECURRENT HÆMORRHAGE.—By Secondary Hæmorrhage is meant bleeding which comes on after the employment of any of the above-mentioned modes of arresting hæmorrhage at any period after the first twenty-four hours. This accident may arise from a variety of causes, which may be divided first into two great classes :—1. Constitutional Causes ; and 2. Local

Constitutional Causes.—It has already been pointed out that the healthy contraction of a wounded artery is a process analogous in every respect to union by the first intention ; the internal coagulum serving the important purpose of protecting the soft new tissue, by means of which the mouth of the wounded vessel, when being closed, is freed from the direct impulse of the wave of blood from the artery. All those constitutional conditions which have already been described as unfavourable to union by the first intention, are therefore equally

CHAPTER XV.

TRAUMATIC ANEURISM AND ARTERIO-VEINOUS WOUNDS.

TRAUMATIC ANEURISM.

WE have hitherto discussed those wounds of arteries in which the blood is discharged freely from an open wound, but all cases are not so simple as these. It sometimes happens that there is a subcutaneous extravasation, forming a more or less distinct cavity, into which the blood is thrown from the wounded artery, accompanied usually by pulsation of the swelling, and occasionally by thrill and bruit. This extravasation constitutes a **Traumatic Aneurism**, and may arise in three ways: 1. The punctured wound leading to the injured artery may be oblique or indirect, and thus the blood may partly escape at the cutaneous opening, and partly be extravasated into the tissues around the vessel. 2. The puncture in the integuments may be closed by plaster, or a pad of lint and a bandage, and thus no blood may escape externally, although the wound in the artery remains patent, and blood is forced out into the substance of the part. 3. There may be no external wound, the artery being punctured or torn subcutaneously by the fragments of a fractured bone, by a violent strain, by the injury inflicted in a dislocation, or by the Surgeon in his efforts to reduce it.

Two forms of aneurism are described as arising from such injuries as the above: the diffused and the circumscribed.

DIFFUSED TRAUMATIC ANEURISM.—This consists of an effusion of blood from a wounded or ruptured artery, limited in extent by the resistance of the surrounding parts. In the immediate neighbourhood of the opening in the vessel there is an ill-defined cavity communicating with the artery formed by the separation of the surrounding parts by the pressure of the blood. There is no true sac, and such boundary as there may be is formed partly by conglutium, and partly by the surrounding fasciæ, muscles and other structures more or less matted together by inflammatory exudation. The extravasation continues to increase and to force its way amongst the tissues of the part until the resistance offered by the stretched and distended structures is equal to the pressure in the injured artery.

The effects of subcutaneous arterial hæmorrhage necessarily vary with the size of the artery, the nature of the wound, and the laxity of the surrounding parts. Thus, if the axillary artery be lacerated in the attempted reduction of an old dislocation of the shoulder-joint, the axilla, the loose tissue beneath the pectoral muscles and in the root of the neck, may be tensely distended with extravasated blood in a few minutes, while in a punctured wound of a deep-seated smaller vessel, such as the posterior tibial, many hours or even days may elapse before the extreme limit of distension of the surrounding parts has been reached. Many Surgeons, with much reason, object to the use of

and "aneurism" in connection with the more rapid arterial extravasations.

clean an artery perfectly, even when using an absorbable ligature. Secondary hæmorrhage may result from sloughing of the vessel, if, in the process of cleaning it for passing the ligature, it be too widely separated from the sheath.

3. *Causes dependent upon the anatomical conditions of the artery at the point ligatured.*—The rush of blood through a neighbouring trunk or collateral branch immediately above the ligature has been considered likely to interfere with the formation of the internal coagulum; but too much importance should not be attached to this, for Porter tied the carotid successfully within one-eighth of an inch of the brachio-cephalic artery; Bellingham ligatured the external iliac close to its origin; and Aston Key, the subclavian in the vicinity of a large branch, without secondary hæmorrhage ensuing. But although the ligature may be safely applied near a branch on its proximal side, I think that the presence of a collateral branch in close proximity to the distal side of the ligature—more especially if it be one that serves to carry on the anastomosing circulation—will be found to have a decided tendency to prevent the occlusion of the distal end of the artery, and thus to favour the occurrence of secondary hæmorrhage.

Bleeding, resembling true secondary hæmorrhage, may occasionally take place some days after the artery is tied, when the collateral circulation is fully established, if the Surgeon have neglected to secure the distal as well as the proximal end.

4. *Pathological conditions of the coats of the artery.*—Chronic endarteritis and calcification of the arterial wall were very important elements in the causation of secondary hæmorrhage after the use of the irritating separable ligature; the process of repair was interfered with and the ligature separated prematurely. The danger is much less with aseptic absorbable ligatures, especially if they be tied with division of the inner and middle coats.

Fatal secondary hæmorrhage has occurred from a large artery, such as the femoral, in consequence of a small atheromatous or calcareous patch having given way immediately above the ligature a day or two after its application.

5. *Unhealthy processes occurring in the wound.*—The extreme rarity of secondary hæmorrhage after operations at the present day is undoubtedly due to the use of aseptic absorbable ligatures, and the prevention of unhealthy changes in the wound. By these means, and by the use of torsion, favourable results are now obtained, even though many of the other predisposing causes of secondary hæmorrhage be present. The occurrence of suppuration around the injured part of the artery necessarily interferes with that healthy process of repair by which the hæmorrhage is permanently arrested. Severe secondary hæmorrhage may occur, especially after gun-shot wounds, as the result of sloughing of the wall of an artery which was bruised, but not actually torn, by the injury.

Phænomena.—The occurrence of secondary hæmorrhage is usually somewhat gradual, and not without warning. The blood does not burst forth in a sudden gush, but appears at first in small quantity, oozing out of the wound and staining the dressings; it may then cease to flow for a time, probably from the opening in the artery becoming plugged by a piece of clot, but it breaks out again in the course of a few hours, welling up freely in the wound, and either exhausting the patient by repeated losses, or else debilitating him so that he falls a victim to some secondary disease, such as pneumonia, erysi-

pelas, or pyramis. In other cases again, after a few warnings, the blood may burst out in a gushing stream that quickly destroys life.

The opportunities which I have had of examining the state of the vessels in several cases of fatal secondary hæmorrhage, lead me fully to concur with Guthrie and Porter, that when hæmorrhage occurs from an artery ligatured in its continuity, the blood in the great majority of instances comes from the distal and not from the proximal side of the wound. The greater tendency in the distal end of the vessel to bleed, appears to arise partly from the less perfect occlusion of this portion of the artery, and partly from its greater liability to slough, in consequence of the ligature interrupting its supply of blood through the vasa vasorum. It is no objection to this opinion that the hæmorrhage is often arterial: for, though it is true that the blood which is carried to the distal end is, for the first few days after the application of a ligature, of a venous hue, yet, after the collateral circulation is freely established, it assumes a more scarlet tint, and at last becomes completely arterial.

Period at which it occurs. Secondary hæmorrhage may occur at any time from twenty-four hours after the operation to the closure of the wound.

When the *separable ligature* was used, it was particularly apt to occur about the period of the separation of the ligature, as the result of any of the causes already specified which interfere with the formation of the internal coagulum, or that occasion ulceration and sloughing of the coats of the vessel. At a later period it might also arise when the wound remained open, as the result of the presence of a slough where the noose of the ligature had lain, or from insufficient drainage of the suppurating track left by the ligature.

In St. Thomas's Hospital is a preparation of a carotid artery, from which secondary hæmorrhage took place in the tenth week after ligature: and South mentions a case of ligature of the subclavian in which the thread separated on the twenty-seventh day, the fatal hæmorrhage occurring in the thirteenth week.

When an *absorbable ligature* is used, secondary hæmorrhage may very rarely occur on the third or fourth day, from premature softening of imperfectly prepared catgut, if that material be employed. Should the ligature be septic, or become so by contamination from the wound, it may behave exactly as the old separable ligature, and secondary hæmorrhage result from similar causes and at similar periods.

Prevention of Secondary Hæmorrhage.—In all cases in which a large artery has been wounded, or tied in its continuity, care should of course be taken to prevent this accident, if possible, by keeping the patient perfectly quiet, avoiding undue stimulation, and keeping the bowels open. A patient once nearly died in University College Hospital from secondary hæmorrhage which commenced while she was straining violently at stool. When there is marked arterial tension with a full and rapid pulse it may sometimes be advisable to have recourse to venesection if from the state of the wound there is any special fear of secondary hæmorrhage. Of all means of avoiding this the prevention of septic processes in the wound is by far the best. Secondary hæmorrhage may be said never to occur in a healthy artery without suppuration. Should suppuration occur and

wound open up so that the main vessels can be seen beating forcibly, the fear of the patient is great. He should then be carefully watched, the diet be lowered, and the artery compressed digitally at the most convenient point above the wound.

TREATMENT OF SECONDARY ARTERIAL HÆMORRHAGE.—In this we are guided by two definite rules to which there are few exceptions: 1. *That even if hæmorrhage have ceased spontaneously, operative interference is necessary to prevent its return*; and, 2. *That the means of arresting the hæmorrhage should, if possible, be applied at the bleeding point.* These principles are now universally recognised, and form the only safe guide in the treatment of this most anxious complication.

That even if the hæmorrhage have ceased spontaneously, operative interference is necessary to prevent its return.—This rule, it will be observed, is the reverse of that by which we are guided in primary hæmorrhage. It is founded on our knowledge of the phenomena of secondary hæmorrhage as described on p. 455. After the first outbreak, even though bleeding may cease for a time, it is almost certain to recur. When a second effusion of secondary hæmorrhage has taken place, the patient's condition becomes most critical; the efforts of nature can no longer be relied on to stop the bleeding, and the fatal gush may recur at any moment. In such circumstances are more coolness and more surgical knowledge required. In adopting a decisive and immediate line of action in a case of secondary hæmorrhage. There is no time for delay, no time for consultation, no time for reference to books; the Surgeon must act at once on his own responsibility.

The only exception to this first rule is when the hæmorrhage occurs a few days after the operation, and is very small in quantity, amounting to no more than a slight oozing. Under these circumstances, elevation of the part, the application of cold and moderately firm bandaging over non-wool or other elastic dressing, so as to press the surfaces of the wound against each other, will sometimes arrest the bleeding. If the hæmorrhage continue, however, more efficient means must be adopted without delay.

That the means of arresting hæmorrhage should, if possible, be applied at the bleeding-point.—This rule is the same as that for primary hæmorrhage. The following are the chief reasons upon which it is founded. *First*, until the wound is opened up it is impossible to determine what vessel the bleeding proceeds. Thus after amputation of the arm it may come from branches of the profunda or from the superficial arteries. In some cases it may happen that no large vessel is bleeding, the hæmorrhage proceeding from the soft granulation-tissue lining an unhealthy wound. In 1866 a man was admitted into University College Hospital under the name of Mr. Jones on account of very serious secondary hæmorrhage from a gun-shot wound on the inner side of the arm, exactly in the line of the brachial artery, which it was supposed to proceed. The wound was freely enlarged and the cavity was exposed lined with soft unhealthy granulation-tissue, but no vessel was found to be bleeding. The cavity was cleaned out and the hæmorrhage did not recur. Twenty years afterwards the man was admitted for a second accident, and the brachial artery could then be seen running close to the wound and evidently uninjured. *Secondly*.—If the main trunk be tied at a

artery, met with in the dissecting-room of University College, a tortuous vessel, about the size of a crow-quill, and measuring, when straightened out, nine inches in length, was found passing from the internal mammary in the third intercostal space to the external mammary branch of the axillary. Occasionally a number of such arteries may form an interlacement. The anastomosing arteries that carry on the circulation are, as a rule, easily dissected out in a well-injected subject in the dissecting-room, and at one time it was supposed that it was not safe to tie a large artery except in those situations in which such easily demonstrable anastomoses exist. Thus, for instance, after the ligation of the common carotid, the supply of blood is ultimately conveyed by the anastomulations between the superior and inferior thyroid arteries and by the vertebral. When the subclavian is tied the circu-

Fig. 147.—Anastomosing Circulation in Posterior and Ventral parts of Dog, three months after Ligation of Femoral. (After Porta.)

Fig. 149.—Clasp in the T and after Ligation with Anastomosing Vessels.

lation of the upper extremity is carried on by the anastomosis of the posterior scapular and suprascapular from the thyroid axis, with the acromio-thoracic and subscapular of the axillary, of the branches of the internal mammary and intercostal arteries with the external mammary of the axillary, and of the superior intercostal of the subclavian with the superior thoracic of the axillary; and when the external iliac is tied, the blood is conveyed to the lower limb by the anastomulations between the internal mammary and lumbar arteries and the epigastric and circumflex ilii, and by those between the obturator, gluteal, and sciatic arteries, and the circumflex branches of the profunda femoris.

It has, however, repeatedly been shown that the ordinary muscular and cutaneous vessels of the part are amply sufficient to carry on the circulation, even when no anastomosing arteries can be demonstrated by dissection.

sion in all directions. Pulsation may, however, be absent. This occurs when the sac is ill-defined and contains much coagulum, and when the cavity is very large in proportion to the artery communicating with it. In spite of the absence of pulsation, such aneurisms continue to increase in size, and may finally rupture, but before doing so the superficial parts covering the tumour become inflamed from the tension. Such non-pulsating inflamed aneurisms are readily mistaken for abscesses. A bruit may often be heard in a circumscribed traumatic aneurism, but it is frequently absent. As the tumour increases in size, it will give rise to pressure signs similar to those of a spontaneous aneurism. (See Chap. XLIII., Vol. II.) This form of traumatic aneurism most commonly occurs from wounds partially dividing small arteries, as the temporal, plantar, palmar, radial, and ulnar, but it is also met with in connection with the larger vessels as a consequence of very small punctured wounds.

The **Treatment** must depend on the size and the situation of the artery, and on the degree of definition of the sac. The less defined the sac, that is to say, the more closely the tumour approaches a diffused aneurism, the more imperative it is to treat it by laying open the sac and ligaturing above and below the opening, as described before (p. 466). On the other hand, if the sac be well defined, treatment by compression of the vessel leading to it may be attempted, and is occasionally successful. When this has failed, the operation by laying open the sac is usually to be preferred. The profuse suppuration from the cavity, which was formerly so troublesome, can usually be prevented by clearing away all coagula with a sharp spoon, and adopting efficient antiseptic treatment. In this way, in a case of traumatic aneurism of the ulnar artery in which the sac was as big as a large orange, complete union by first intention was obtained, the two sides of the sac adhering when brought together. In exceptional cases, if the sac be well-defined, and the tumour be so situated that it would be difficult or hazardous to lay it open, a proximal ligature may be applied; but there is no necessity in most cases to tie at a distance from the sac, as the vessel is healthy except at the wounded spot. Thus, to avoid cutting into the palm, which might have endangered the utility of the hand, I successfully tied the brachial for the aneurism represented in Fig. 150, which followed an injury from a powder-flask explosion. When the aneurism shows signs of impending suppuration the proper course is to lay open the sac and tie above and below.

Fig. 150. Circumscribed Traumatic Aneurism in Ball of Thumb after a Powder-flask Explosion.

2. The next form of circumscribed traumatic aneurism is of rare occurrence, and arises usually from a small puncture in a large artery. The vessel bleeds freely; but, the hæmorrhage being arrested by pressure, the external wound, and that in the artery close. The cicatrix in the artery gradually yields, forming, at the end of weeks or months, a tumour which gradually enlarges, and pulsates eccentrically, with distinct bruit, having all the symptoms that characterize an aneurism from disease, and possessing a sac continuous with

Surgeons appear to have been led away by the erroneous idea of applying the Hunterian principles in the treatment of aneurism of that of wounded arteries, until Guthrie, by his practice and precepts, and by bringing an overwhelming mass of proof to bear on this important question, recalled the attention of the Profession to the proper and rational treatment of wounded arteries.

1. That no operation ought to be performed on a wounded artery unless it bleeds.—If by the time the Surgeon sees the patient, bleeding has ceased, however furious it may have been, and however probable it may appear from the situation of the wound that a large artery has been injured, no operation should be undertaken. The patient should be placed in bed, the wound should be dressed and a tourniquet applied loosely round the limb, ready to be tightened at once should the bleeding again occur. He should be constantly watched by some competent person for the next twenty-four or forty-eight hours. If, before the Surgeon sees the case, bleeding supposed to come from a large vessel has been arrested by pressure, he should at once relax all pressure and remove the pads, as it is not safe to trust to compression for the arrest of hæmorrhage from a vessel of any magnitude. If, on doing this, bleeding occurs, he must be guided in his treatment by the two following rules. If no hæmorrhage appears, he must follow the directions just given. The reason for this rule is that a small artery, especially when wounded near its parent trunk, may for a time pour forth such an amount of blood as to make it appear as if the main trunk itself was implicated, and yet may safely be closed by the processes of natural arrest already described. A man was brought to the University College Hospital with a deep stab in the groin, directly in the course of the external iliac artery; a very large quantity of arterial blood had been lost, but the hæmorrhage was arrested on his admission by the application of pressure, &c. From the great and sudden loss of blood it was supposed that the external iliac had been punctured, but it was not thought advisable to perform any operation unless hæmorrhage resumed. The bleeding did not return, and the wound healed without any further trouble.

This rule, as will subsequently be shown, does *not* apply to secondary hæmorrhage, nor to bleeding from vessels opened by ulceration or sloughing.

2. To expose the vessel at the wounded part and to tie it there.—The principal reason for this rule is, that a ligature of the main trunk at a distance above the wound stops only the direct supply of blood to the limb, but does not interfere with the indirect or anastomosing circulation, by which means the blood readily passes into that portion of the vessel which is beyond the ligature, and may, if the anastomosis be very free, continue to escape from the divided artery. Thus, though bright arterial blood may no longer jet from the wound, a continuous stream of the same colour, or of a darker tint if it has become partially deoxygenated in its passage through the anastomosing channels, will continue to well out. This may come from the proximal or the distal end, or from both, but most commonly from the distal end only. If the anastomosis is less free, ligature at a distance on the proximal side may temporarily arrest the hæmorrhage by the formation of a clot at the seat of the wound, but as the anastomosing circulation becomes fully established and the blood-pressure increases, the clot is forced out and hæmorrhage recommences. Thus, if a Surgeon endeavours to arrest the flow of blood from a wound of the ulnar artery near the palm by a ligature applied to the brachial in the middle

of the arm, and, when the blood bursts forth as furiously as ever, applies successive ligatures to the arteries of the forearm with as little success, he will at last, on account of the continual recurrence of hæmorrhage, be forced to adopt the simple expedient that ought to have been had recourse to in the first instance, namely, that of ligaturing the vessel at the point wounded.

Another reason for the practice now advocated is, that in some cases the surgeon cannot possibly know what artery is injured unless he seek for it in the wound itself. A large artery may, from the direction of the stab and the impetuous flow of blood that has followed it, appear to be wounded, when in reality it is only a minor branch that has been injured. Thus, for instance, in hæmorrhage from a stab in the axilla, which proved fatal notwithstanding the ligature of the subclavian artery for supposed wound of the axillary, the long thoracic was found to be the vessel divided; so, also, the external iliac artery has been ligatured for supposed wound of the common femoral, when in reality it was the external pudic that was injured.

Lastly, when the main artery of a limb is wounded, if ligature of the trunk in its continuity on the proximal side of the wound should by any chance succeed in arresting the bleeding, the vessel is obliterated at two points—at the seat of ligature and at the wound—and, consequently, gangrene is very likely to occur as the blood may have to pass through two sets of anastomosing vessels to reach the parts below the wound.

This rule applies to every case in which it is possible to expose the wounded vessel sufficiently to apply a ligature to it. The only exceptions are wounds of certain of the deep branches of the carotid and some cases of wound of the deep palmar arch (see Chapter XVI). As will be seen hereafter it applies to secondary as well as to primary hæmorrhage.

3. The third great principle in the treatment of wounded arteries is, that **a ligature is to be applied to both ends of the vessel, if it be completely cut across; or on both sides of the aperture in it, if it be only partially divided.**

The reason for this rule of practice is founded on physiological grounds as well as on practical experience. If the anastomoses of the part be very free, as in the arteries of the palm or forearm, bleeding may continue from the distal end, uninterrupted by the ligature on the proximal side of the wound; if they be less free, a stream of dark-looking venous blood will probably issue in the course of two or three days. After the collateral circulation has been sufficiently established, bright scarlet blood will burst forth from the distal aperture. Experience has shown that it is in this way that secondary hæmorrhage from wounded arteries commonly occurs, the bleeding coming from the distal and not from the proximal end of the vessel.

In some cases the distal end is so retracted and covered in by surrounding parts, that it cannot be found in order to be ligatured. In these circumstances, if it is not actually bleeding, it may be left alone in the hope that hæmorrhage will not occur. If, however, it be bleeding, a graduated compress must be applied, but such means should never be resorted to until the wound has been freely enlarged and a thorough search made for the vessel. If an arterial branch happen to be divided so close to its origin that it cannot be secured, the case must be treated as one of puncture of the main trunk, which must be ligatured above and below the bleeding orifice.

Mode of Operating.—In order to arrest the hæmorrhage during the

operation a tourniquet should be applied if the wounded vessel is in one of the limbs. A screw tourniquet will usually be found most convenient, as it can be relaxed in order to guide the Surgeon to the wound when the vessel is exposed, and again tightened with little loss of time. It is more effectual and certain than digital compression by an Assistant. It will often be found a great assistance to the Surgeon if the limb be rendered bloodless by Esmarch's method before commencing the operation. While this is being done the hæmorrhage must be arrested by digital compression at the most convenient point above the wound. When the wound is in such a situation that a tourniquet cannot be applied, digital compression by an assistant must necessarily be relied on. Hæmorrhage having been temporarily arrested by one of the above means, a large probe should be passed to the bottom of the wound; and, taking this as the centre, a free incision should be made in such a direction as will best lay open the cavity with the least injury to the muscles and other soft parts. After turning out any coagula contained in the wound, and clearing it as well as possible, the injured vessel must be sought for. The situation of this may sometimes be ascertained at once by the gaping of the cut in its coats; but, in many cases, it is necessary to relax the pressure upon the artery, so as to allow a jet of blood to escape, and thus indicate the position of the aperture. If the vessel be only partially divided it must be cleaned in the way already described when treating of ligatures of arteries in their continuity, and a ligature passed by means of an aneurism needle above and below the wound. When these are tied it is safer to divide the vessel completely at the site of the wound. If the vessel has been completely cut across, each end must be found and drawn forward with the artery forceps and tied as in an open wound. This operation is not always so easy in practice as it seems in description. The artery, if completely divided, retracts considerably, and it is often difficult to find the ends in the midst of the areolar tissue infiltrated and stained with blood. Under these circumstances a portion of the sheath thickened by adherent coagulum may be mistaken for the artery. The proximal end is most commonly found with little difficulty by allowing a jet of blood to escape from it. The distal end may not be bleeding at the time of the operation, though blood would probably escape from it as soon as the anastomosing circulation became established. It can then only be found by a careful search guided by accurate anatomical knowledge.

The artery is usually reached most easily by enlarging the original wound in the parts superficial to it, but Guthrie advises that, in those cases in which the wound passes indirectly to the principal artery from the back or outside of the limb, the Surgeon instead of following the track of the wound, shall cut down on the vessel where it lies nearest the surface; then, on passing a probe through the wound, the spot at which the artery has probably been injured will be pointed out, and the ligature must then be applied in the way usual in cases of primary hæmorrhage.

ACCIDENTS AFTER ARTERIAL OCCLUSION BY SURGICAL MEANS.

The accidents that may follow the arrest of primary hæmorrhage from a wounded artery are Intermittent or Reactionary Hæmorrhage, Secondary or Recurrent Hæmorrhage, and Gangrene of the Limb.

INTERMEDIATE OR REACTIONARY HÆMORRHAGE.—This term is limited to hæmorrhage occurring within twenty-four hours of the wound of the vessel. It most commonly occurs within twelve hours of the infliction of the injury.

Causes.—At the end of an operation the patient is often faint from the combined shock, loss of blood, and the depressing influence of the anæsthetic; at the same time the exposure of the wound to the air, and the mechanical stimulus of the knife and the sponges, have caused the greatest possible degree of contraction of the mouths of the wounded vessels. Under these circumstances, vessels of considerable size may not yield a drop of blood. As soon as the wound is closed, however, and warmly dressed, and the patient put to bed, the faintness begins to pass off, the heart beats more forcibly, the contracted vessels dilate, and hæmorrhage takes place. At the same time, if any vessel have been imperfectly tied—owing to carelessness on the part of the Surgeon, or to the use of badly-prepared rigid catgut—the knot may yield, and the suture may slip off.

The *wound of a collateral branch* above the point of application of the suture, though it does not bleed much at the time, will, as I have seen, cause furious bleeding as the collateral circulation becomes established.

Phenomena.—As the bleeding comes as a rule only from the smaller vessels, it is seldom very profuse. It usually distends the wound, tightening the stitches, and causing the patient considerable pain.

Treatment.—Stimulants should be avoided as far as possible during the first few hours after an operation, so that recovery from shock may be gradual. The local treatment is the same as that of primary hæmorrhage. If the oozing be very slight, the part may be raised and gentle pressure applied; if more abundant, the wound must be opened up, and the bleeding vessel secured. If the wound is much distended by clots, the pressure thus produced may arrest the bleeding; but it is better for the patient under these circumstances to open up the wound, turn out the clots, and secure any vessel that may be found, as the mass of coagulum between the surfaces would form a serious obstacle to union by the first intention.

If at an operation the patient be very faint, and the smaller arteries which might be expected to bleed cannot be found, they may sometimes be made apparent by bathing the wound with carbolic lotion or some other antiseptic solution at a temperature of about 98° Fahr. In private practice it is better to do all operations if possible early in the morning, so that if reactionary hæmorrhage should occur, it may take place in the day and not in the night.

SECONDARY OR RECURRENT HÆMORRHAGE.—By Secondary Hæmorrhage is meant bleeding which comes on after the employment of any of the above-mentioned modes of arresting hæmorrhage at any period after the first twenty-four hours. This accident may arise from a variety of causes, which may be divided first into two great classes:—1. Constitutional Causes; and 2. Local Causes.

Constitutional Causes.—It has already been pointed out that the healthy closure of a wounded artery is a process analogous in every respect to union by first intention: the internal coagulum serving the important purpose of protecting the soft new tissue, by means of which the mouth of the wounded vessel is being closed, from the direct impulse of the wave of blood from the heart. All those constitutional conditions which have already been described as being unfavourable to union by the first intention, are therefore equally

unfavourable to the closure of a wounded artery, and consequently act as predisposing causes of secondary hæmorrhage. In some cases of *septicæmia* and in *pyæmia* the blood is found to coagulate imperfectly, and in these the internal coagulum may be more or less completely wanting, thus exposing the feeble granulation-tissue, closing the vessel, to the direct impulse of blood from the heart. In such cases, even if a clot of blood does form at first, it is liable to disintegrate and to be washed away.

In some cases secondary hæmorrhage appears to be in part due to the *forcible and excited action of the heart during the early stages of traumatic fever*.

The patient is restless, and the pulse quick and bounding. In such circumstances if the bleeding be not too profuse, it sometimes appears to give relief to the symptoms.

Chronic Bright's disease, with increased arterial tension and hypertrophy of the heart, sometimes acts as a predisposing cause of secondary hæmorrhage, which is also more likely to occur in plethoric subjects, than in those of a more spare habit.

Local Causes.—These may be thus divided :—

1. *Causes dependent on the Ligature.*—A silk or hemp ligature applied in such a way as to cut through the arterial coats and to come away from the wound, necessarily excited inflammation, reaching the stage of suppuration, and maintained the process till it had cut through the vessel by ulceration. The extent of the inflammation depended to some degree upon the size of the ligature. If it were very fine and well waxed so as to be almost non-absorbent the inflammation was accurately limited to the parts in contact with the thread. If, however, it were thick and soaked in decomposing discharges, the inflammation extended more widely and interfered with the proper development of the granulation-tissue closing the divided inner and middle coats; consequently, as soon as the process of ulceration had perforated the external coat, hæmorrhage occurred. It had long been recognized that the finer the ligature, the more safely did it occlude the vessel, provided it were of sufficient strength to divide the inner and middle coats when tightened. The thicker the ligature, the more irritation it caused, and the more speedily it ulcerated through the external coat of the artery.

If the ligature be absorbable it should, as before stated, give rise to suppuration in its immediate neighbourhood. It may, however, prove irritating, if it be improperly prepared, or if it be allowed to come in contact with decomposing discharges. Some of the absorbable ligatures also present the danger of premature softening, in consequence of which the support of the constricted external coat is taken away from the soft new tissue closing the vessel, before it is sufficiently strong to resist the blood-pressure within the artery.

2. *Causes dependent on the mode of application of the ligature.*—If the artery were insufficiently cleaned, and other structures, as pieces of muscle or a neighbouring nerve, were included in a non-absorbable ligature, the vessel was seldom safely occluded; first, because its coats were not properly divided, and secondly, because of the more extensive sloughing and ulceration resulting from the inclusion of so large a mass in the noose of the ligature. With absorbable ligatures the dangers arising from imperfect cleaning are much less, as the ligature does not separate by ulcerating through the mass included in its noose; but no Surgeon would on this account relax his endeavours to

occlude an artery perfectly, even when using an absorbable ligature. Secondary hæmorrhage may result from sloughing of the vessel, if, in the process of loosening it for passing the ligature, it be too widely separated from the sheath.

3. *Causes dependent upon the anatomical conditions of the artery at the point of ligature.*—The rush of blood through a neighbouring trunk or collateral branch immediately above the ligature has been considered likely to interfere with the formation of the internal coagulum; but too much importance should not be attached to this, for Porter tied the carotid successfully within one-eighth of an inch of the brachio-cephalic artery; Bellingham ligatured the external iliac close to its origin; and Aston Key, the subclavian in the vicinity of a large branch, without secondary hæmorrhage ensuing. But although the ligature may be safely applied near a branch on its proximal side, I think that the presence of a collateral branch in close proximity to the *distal* side of the ligature—more especially if it be one that serves to carry on the anastomosing circulation—will be found to have a decided tendency to prevent the occlusion of the distal end of the artery, and thus to favour the occurrence of secondary hæmorrhage.

Bleeding, resembling true secondary hæmorrhage, may occasionally take place some days after the artery is tied, when the collateral circulation is fully established, if the Surgeon have neglected to secure the distal as well as the proximal end.

4. *Pathological conditions of the coats of the artery.*—Chronic endarteritis and calcification of the arterial wall were very important elements in the causation of secondary hæmorrhage after the use of the irritating separable ligature; the process of repair was interfered with and the ligature separated prematurely. The danger is much less with aseptic absorbable ligatures, especially if they be tied with division of the inner and middle coats.

Fatal secondary hæmorrhage has occurred from a large artery, such as the femoral, in consequence of a small atheromatous or calcareous patch having given way immediately above the ligature a day or two after its application.

5. *Unhealthy processes occurring in the wound.*—The extreme rarity of secondary hæmorrhage after operations at the present day is undoubtedly due to the use of aseptic absorbable ligatures, and the prevention of unhealthy changes in the wound. By these means, and by the use of torsion, favourable results are now obtained, even though many of the other predisposing causes of secondary hæmorrhage be present. The occurrence of suppuration around the injured part of the artery necessarily interferes with that healthy process of repair by which the hæmorrhage is permanently arrested. Severe secondary hæmorrhage may occur, especially after gun-shot wounds, as the result of sloughing of the wall of an artery which was bruised, but not actually torn, by the injury.

Phænomena.—The occurrence of secondary hæmorrhage is usually somewhat gradual, and not without warning. The blood does not burst forth in a sudden gush, but appears at first in small quantity, oozing out of the wound and staining the dressings; it may then cease to flow for a time, probably from the opening in the artery becoming plugged by a piece of clot, but it breaks out again in the course of a few hours, welling up freely in the wound, and either exhausting the patient by repeated losses, or else debilitating him so that he falls a victim to some secondary disease, such as pneumonia, erysi-

to allow of the temporary arrest of the bleeding by digital pressure below the carotid tubercle, this should be at once done. The wound must then be enlarged, and if possible, the artery tied above and below the bleeding point, parts of one or more of the transverse processes being removed, if necessary. Failing this, the Surgeon must resort to careful plugging of the wound, or he may be able to seize the bleeding vessel in forcipressure-forceps and leave them *in situ* for several days.

Traumatic Aneurism of the Vertebral Artery has been recorded in twenty cases by Matus, of which six recovered, one of these being a case of his own, in which the sac was freely laid open in the suboccipital region and the hæmorrhage successively arrested by plugging. This treatment would appear to give the best hope of success, if digital compression of the artery and direct pressure on the aneurism fail to produce a cure.

VESSELS OF THE TRUNK.

INTERNAL MAMMARY.—Wounds of this artery rarely come under treatment as its course lies chiefly in front of the heart and great vessels, so that penetrating wounds implicating it are usually immediately fatal from injury to the parts beneath. The *treatment*, in case the patient escapes fatal injuries to deeper parts, is to tie the artery at the wounded spot, if necessary removing a costal cartilage in order to expose it. No other treatment is likely to arrest the bleeding, because of the free anastomoses with the intercostals.

INTERCOSTAL ARTERIES.—These are rarely wounded except in gunshot wounds or stabs fracturing a rib. The hæmorrhage is seldom severe; but should it require *treatment*, the lower border of the rib corresponding to the artery must be exposed by a free incision. On removing the fragments the bleeding artery may come into view, and can be twisted or tied; or it may be turned out of its groove by means of a periosteal elevator, and sufficiently exposed to be tied. If necessary, a piece of rib may be removed to lay bare the vessel more fully. As a temporary means, pressure can be applied thus:—A piece of linen is to be pushed through the wound into the pleural cavity, so as to form a pocket: inside a sufficient quantity of lint or tow is pushed into the pocket to make it too large to pass out by the intercostal space: it is then forcibly pulled upon by the part of the linen outside the chest-wall, and secured in position by a couple of pins pushed across on a level with the skin.

VESSELS OF THE UPPER LIMB.

SUBCLAVIAN ARTERY.—Wounds of the Subclavian Artery are almost invariably fatal; though, owing to the protection afforded by the clavicle, they rarely occur except from gunshot injuries or stabs. From the rapidly fatal nature of wounds of the subclavian artery, **Traumatic Aneurisms** in this situation are not met with; but where the artery passes into the axilla below the margin of the first rib, they are not unfrequent.

Aneurismal Varix, resulting from wound of the Subclavian Artery and Vein, has been seen, notwithstanding the separation that exists between the two vessels throughout their whole extent. These injuries have likewise usually been the result of sword-thrusts, and do not admit of any surgical interference.

AXILLARY ARTERY.—In **Open Wounds of the Axillary Artery and its Branches**, the rule of practice is to expose the bleeding vessel and tie it on each side of the wound. The branches of the artery are so numerous that there must always be some uncertainty, in a case of punctured wound, whether the main trunk or a branch is injured, even when the direction of the wound and the abundance of the bleeding would suggest the former. This doubt can be cleared up only by exposing the bleeding point, and in order to do this efficiently, it may sometimes be necessary to divide both the pectoral muscles across the line of their fibres.

In secondary hæmorrhage, the state of the parts may be such as to make it very difficult to expose the artery cleanly in the wound, and the temptation to apply a proximal ligature under these circumstances is very strong, but this should never be done before a thorough attempt has been made to tie the vessel at the bleeding point, by freely opening up the wound and enlarging it, if necessary. The anastomoses between the branches of the subclavian and the axillary are so free that ligature of the third part of the subclavian is extremely likely to fail. Ligature of the first part of the axillary artery would, in a case of secondary hæmorrhage, be just as difficult as exposing the bleeding point, and could be done after division of the pectoralis major and minor, should it be impossible to secure the vessel at the wounded point. In a case of secondary hæmorrhage, the ligature of the first part of the axillary by a curved incision below the clavicle, as described in Chap. XLIV., Vol. II., would be most difficult; as the axilla would probably be filled with extravasated blood, and the parts matted together by the inflammation and suppuration which caused the failure in the repair of the artery. In all cases of secondary hæmorrhage, it would be safer to expose the artery by an incision in the line of the vessel dividing the pectoral muscles. The subclavian must be tied above the clavicle only as a last resource. The operation has been attended with success enough to justify its adoption should other means fail. Of 15 cases in which it has been performed for hæmorrhage from wounds in the axilla or from stumps, I find that 9 were cured and 6 died.

Traumatic Aneurism in the Axilla may arise from gunshot wounds or stabs, or in some cases from subcutaneous rupture of the vessel. In the latter case the patient while straining his arm in a raised position feels a sudden snap, which is rapidly followed by a large extravasation of blood in the axilla, forming the so-called diffused traumatic aneurism.

There are more than 40 cases on record in which axillary aneurism has followed an injury to the vessel occurring during the reduction of a dislocation. In only a few of these has the dislocation been recent. Amongst these is one recorded by Warren in which the vessel was ruptured in consequence of the Surgeon using his foot in the axilla as a fulcrum, but without taking off his boot. In the great majority of cases the dislocation has been of old-standing, and considerable force has been used. Gibson has related three cases of rupture of the artery in the attempt to reduce such cases by the pulleys. Pelletan mentions a case in which the rapid swelling following the rupture of the artery was mistaken for emphysema from fractured ribs. An incision was made into it and the patient bled to death. These cases show the necessity for great caution in the use of powerful extending force in the reduction of old dislocations, when adhesions may have formed between the artery and the head of the bone.

distance on the proximal side, if the operation succeeds in arresting the bleeding, the artery will be obliterated in two places, at the seat of ligature and at the wound, and, for the reasons already given, gangrene is very likely to occur. *Thirdly.*—If the anastomosing circulation is so free that gangrene does not occur, it is very probable that the operation of ligature at a distance would fail to arrest the bleeding. *Fourthly.*—The ligature of the main trunk on the proximal side involves the performance of a serious operation on a patient in a most unfavourable condition from loss of blood and septic fever, and possibly also from some infective process such as erysipelas, hospital gangrene, or pyæmia. *Fifthly.*—As secondary hæmorrhage almost invariably occurs as a consequence of septic inflammation and suppuration in the wound, the patient's condition is usually improved by opening it up and cleaning it out with some efficient antiseptic. For this reason the patient will in most cases be benefited by the attempt to secure the bleeding vessel in the wound, even if the operation cannot be completed, and the Surgeon is driven as a last resource to tie the vessel at a distance on the proximal side.

The only argument of any weight which has been brought forward against the rule of operating at the bleeding point is that as the first ligature has failed, probably from the unhealthy condition of the wound, the second ligature is likely to fail also from the same cause, and that if, in order to reach a healthy part, the artery is exposed at a higher point by an incision continuous with the original wound, the fresh raw surface will inevitably be infected from the foul wound. Against this it may be urged that it is very possible that the fresh incision, even if made at a distance, may become infected with the unhealthy process affecting the original wound, especially in cases of erysipelas, hospital gangrene, or wound diphtheria, and thus nothing would be gained by applying a ligature at a distance on the proximal side. Moreover, when the wound is freely opened up it may, in most cases, be brought into a healthy condition by the free application of some powerful antiseptic, such as chloride of zinc (gr. 40 to 3j.), or perchloride of mercury (1 in 500), and afterwards dusting the surface with iodoform, and applying some antiseptic dressing.

For these reasons it may be stated as a general rule, to which there are but few exceptions, that however deep the wound, and however unhealthy the neighbouring parts may be, there is no safety to the patient unless the artery be exposed and tied at the part injured. An operation of this kind is often attended with the greatest difficulty, not only owing to the hæmorrhage that usually accompanies it and obscures the parts, but also in consequence of the inflamed, infiltrated, and sloughy condition of the tissues in the wound. In applying the ligature under these circumstances, the tissues will necessarily have in a great degree lost their cohesion and firmness: and although the arterial coats resist the disorganising influence of inflammation much longer than areolar or muscular tissue, yet they will also have become softened and less resistant. Hence the vessel must be isolated with gentleness, and the ligature very carefully applied. In many cases it will be necessary to expose the artery a short distance from the surface of the wound in order to find a part sufficiently healthy to hold the ligature.

The exceptions to this rule are in the first place the same as in primary hæmorrhage, viz., the deep branches of the carotid and some cases of wound

of the deep palmar arch. Secondly, in extremely foul or sloughing wounds, the Surgeon may fail to secure the bleeding point by ligature or other means, and under these circumstances proximal ligature is his only resource. Thirdly, if the bleeding has recurred more than once after ligature in the wound the Surgeon may, as a last chance, apply a ligature to the main trunk at a distant point.

In applying these rules it must be considered whether the bleeding takes place, 1, from a stump; or, 2, from an artery tied in its continuity or ligatured on each side of a wound.

1. The treatment of **secondary hæmorrhage from a stump** will depend partly on the degree of union that has taken place between the flaps, and on the situation of the stump. If the hæmorrhage be no more than a slight oozing, elevation and pressure may arrest it. Should it continue, however, the Surgeon has three courses open to him: separation of the flaps and ligature of the artery at the bleeding point; ligature of the main artery above the stump; and, lastly, re-amputation. The first of these alternatives, viz., *ligature of the artery at the bleeding point*, is universally recognised as the object to be aimed at if the hæmorrhage have occurred early when the flaps are still easily separated, or in later cases when the union has been extensively broken down by the hæmorrhage. But even if, notwithstanding the hæmorrhage, the union between the flap continues sound and firm, the blood flowing merely through a narrow channel leading to the main vessel, this same rule must, in most cases, be followed. The wound must be opened up, all adhesions, however firm, being broken down with the finger, and the artery must be secured at the bleeding point. Besides the main artery that bleeds—one of the tibials, for instance, if it be a leg-amputation—there will generally be very free oozing from many points. The more abundant of these may be stopped by a ligature passed, if the tissues be friable, by means of a navus-needle under the vessels; free general oozing may usually be arrested by clearing the surfaces of the flaps of all coagula, and by the firm uniform pressure of the dressing.

If the tissues are so softened that ligatures will not hold, the actual cautery may be applied to the smaller bleeding points, whilst in the case of the main artery a sufficiently healthy part of the vessel may be reached by separating it for a short distance from the face of the flap. The treatment of secondary hæmorrhage from the main artery by digital compression of the vessel higher on the limb or the use of a horse-shoe tourniquet is too uncertain to be recommended.

In those cases where the amputation has been done close to the trunk, as at the shoulder-joint or the middle or upper part of the thigh, there is less objection to the practice of ligaturing the artery at a higher level instead of opening up the stump. The length of limb to be nourished is so small that there is little fear of gangrene. Even in these cases, however, the Surgeon will be wise to follow the general principle of treatment, and by opening up to a sufficient extent the track from which the blood is escaping, to endeavour to apply a ligature above the bleeding point.

Ligature of the main artery above the stump is the only alternative in those amputations close to the trunk in which the hæmorrhage recurs after an attempt has been made to arrest it by opening up the flaps. In the case of the shoulder the third part of the subclavian should be tied, and in amputa-

tions in the upper part of the thigh a ligature should be applied to ~~the~~ common femoral or the external iliac just above Poupart's ligament. Ligature of the artery at a higher level must also be tried under similar circumstances in all amputations in the upper limb and in amputations in the lower part of the thigh. In such cases, also after amputation of the foot, I have successfully tied the posterior tibial just above the malleolus. Should this not succeed in arresting the bleeding, or be followed by gangrene, *reampulation* is the last resource.

In the case of secondary hæmorrhage from a leg stump below the knee in which the first method of treatment has failed, no good is likely to follow the application of a ligature to the femoral. This either fails to arrest the bleeding or produces gangrene, and thus necessitates reamputation at a higher level than would otherwise be necessary.

2. When the hæmorrhage occurs after ligature of an **Artery in its Continuity**, whether for injury or disease, if the vessel be situated in the *trunk*, as the subclavian, or one of the iliacs, there is nothing to be done but to apply pressure; and in the great majority of these cases the patient will die exhausted by repeated hæmorrhage. In employing pressure a graduated compress should be firmly applied. If this cannot be done, prolonged digital compression in the wound might possibly arrest the bleeding. In a case of ligature of the innominate, Smythe, of New Orleans, arrested the bleeding by pushing a piece of muslin into the wound and filling the pouch thus formed with shot.

When the artery is situated in one of the limbs, if the bleeding has been very slight in amount, pressure may be applied over the point from which the blood proceeds, but if the bleeding has been copious, and more especially if pressure has failed after one trial, more efficient procedures must be employed.

If it be one of the arteries of the *upper extremity* the wound should be opened up and an attempt made to expose the vessel thoroughly. If it has been completely divided by the ligature, the bleeding end only need be tied, but if the hæmorrhage proceeds from an opening formed by ulceration opposite the knot of the ligature, the vessel should be tied above and below the hole in its coats. Should this fail or not be practicable, the artery must be deligated at a higher point than that at which it had previously been tied; should the hæmorrhage continue, or recur, amputation is the only resource left.

In the *lower extremity*, the treatment of secondary hæmorrhage occurring after ligature is surrounded with difficulty. Here I believe it to be useless to tie the artery at a higher point than that to which the ligature has already been applied, as gangrene is very apt to follow this double ligature: at least, in the two or three cases that I have seen in which recourse has been had to this practice, and in all the reported cases with which I am acquainted, mortification of the limb has ensued. The treatment should vary according as we have the femoral artery or one of the tibials to deal with. If the hæmorrhage proceed from the femoral, I should be disposed to cut down on the bleeding part of the vessel, treating it as a wounded artery, and applying a ligature above and below the part already deligated; this operation would, however, necessarily be attended with difficulty. Should it be impracticable, or should the hæmorrhage recur after it has been done, we should best consult the safety

of the patient by amputating on a level with or above the ligature. Although this is an extreme measure, it is infinitely preferable to allowing him to run the risk of the supervention of gangrene, which will require removal of the limb under less favourable conditions. If the secondary hæmorrhage proceed from one of the tibials, it would be all but useless to adopt either of the preceding alternatives. If we ligatured the superficial femoral, the bleeding would not be permanently controlled, or, if it were, gangrene of the limb would in all probability set in. There are very few cases on record in which this practice has been adopted without mortification occurring. In a few rare instances, however, ligature of the popliteal has, in such circumstances, succeeded; but it has also frequently failed, rendering secondary amputation necessary; so its success is a mere matter of chance. The depth at which the tibials are situated is so great, that it would be hopeless to search for one of these vessels and attempt its deligation at the bottom of a deep, sloughy, infiltrated and inflamed wound. In such circumstances, therefore, I think we should amputate the leg above the seat of wound. This is truly a severe measure; but the only alternative that has, to my knowledge, ever succeeded, is ligature of the popliteal; and as that, as already stated, has frequently failed, I think that, as a rule, we should best consult the safety of the patient by the removal of the limb at once.

If the hæmorrhage occur from a wounded artery to which ligatures have already been applied above and below the seat of the wound, the same treatment must be adopted as in those cases in which the bleeding takes place from a vessel tied in its continuity.

Hæmorrhage from arteries opened by ulceration or sloughing must be treated on the same principles as in other forms of secondary hæmorrhage. If the loss of blood has been abundant we must not wait for a recurrence of the hæmorrhage before seeking for the bleeding point, and the ligature should, if possible, be applied above and below the opening in the artery; proximal ligature at a distance being justifiable only when this is impossible, or an attempt to carry it out has failed.

GANGRENE FOLLOWING LIGATURE.—After the ligature of the main artery of a limb, the collateral circulation is, under all ordinary circumstances, sufficient to maintain the vitality of the parts supplied by the deligated vessel. In some cases, however, it happens that the condition of the circulation in the parts below the ligature is not compatible with their life.

The *Period of Supervention* of gangrene of the limb extends over the first three or four weeks after the ligature of the vessel. It seldom sets in before the third day, but most frequently happens before the tenth.

Causes.—The causes influencing the occurrence of gangrene in this way are the Age of the Patient, the Seat of the Operation, and various Conditions in which the limb may afterwards be placed.

The influence of *age* is not, however, so marked as might *a priori* be supposed; for, although there can be no doubt that there is less accommodating power in the arterial system at an advanced period of life to varying quantities of blood, and that there would be greater difficulty in maintaining the vitality of a limb after ligature of its artery in a man of sixty than in one of twenty-five, yet I find that, of thirty cases in which gangrene of the lower extremity followed the ligature either of the external iliac or femoral arteries, the average age of the patient was thirty-five years, as nearly as

possible the mean age at which these operations, according to Norris's Tables are generally performed. Of these cases of gangrene two occurred in persons under twenty years of age, eleven between twenty and thirty, eight between thirty and forty, and nine above forty.

The *seat of the operation* influences greatly the liability to gangrene, which is much more frequent after the ligature of the arteries in the lower than in the upper extremity.

Besides these predisposing causes, gangrene after ligature may be directly occasioned by a *deficient supply of arterial blood*. In some cases this may arise from the collateral vessels being unable, in consequence of the rigidity of their coats, to accommodate themselves to the increased quantity of blood which they are required to transmit; or they may be compressed in such a way by extravasation as to be materially lessened in their capacity. In other instances again, the existence of cardiac disease may interfere with the proper supply of blood to the part.

Great *loss of blood*, either in consequence of secondary hæmorrhage, or from any other cause, before or after the application of the ligature, is often followed by gangrene, and is almost certain to be attended by this result if a second ligature have been applied to a higher point in the lower extremity. That a diminution in the quantity of blood circulating in the system may, under the most favourable circumstances, become a cause of gangrene after the ligature of a main artery, is illustrated by the statement of Hodgson that, soon after the introduction of the Hunterian operation into Paris, it was the custom to employ repeated venesection in the cases operated on; the consequence of which was, that mortification was of frequent occurrence.

A more common cause of gangrene is the *difficulty experienced by the venous blood in its return from the limb*. This difficulty always exists even when no mechanical obstacle impedes the return, being dependent on the want of a proper *vis a tergo* to drive on the blood. The propulsive force of the heart, the main agent in the venous circulation, is largely expended in driving the blood through the narrow and circuitous channels of the anastomosing vessels. This difficulty to the onward passage of the venous blood may, if there exist any cause of obstruction in the larger venous trunks, be readily increased to such an extent as to arrest the circulation, and so cause the limb to mortify. This mechanical obstacle may be dependent upon the occlusion of the vein by thrombosis opposite the ligature, by its transfixion with the aneurism-needle, or by its accidental wound with the knife in exposing the artery. When such an injury, followed by inflammation, is inflicted on a vein, which, like the femoral, returns the great mass of blood from a limb, gangrene is almost inevitable.

The supervention of *erysipelas* in the limb after the application of a ligature, though fortunately of very infrequent occurrence, is a source of considerable danger, being very apt to give rise to gangrene by the tension of the parts obstructing the anastomosing circulation. I have on two occasions seen gangrene of the fingers, from this cause, follow ligature of the vessels of the forearm.

Abstraction of heat from the limb, either directly by the application of cold, or indirectly by the neglect of sufficient precautions to keep up the temperature of the part, often occasions gangrene; thus, Astley Cooper saw mortification follow the application of cold lead lotion to a limb in which the femoral artery

had been tied; and Hodgson witnessed the same result when the operation was performed at an inclement season of the year.

The *incautious application of heat* may occasion mortification, by overstimulating the returning circulation of the limb, especially about the period when the rising temperature indicates distension of the capillary vessels. In this way the application of hot bricks and bottles to the feet has given rise to sloughing; and Liston was compelled to amputate the thigh after ligature of the femoral artery, for gangrene induced by fomenting the limb with hot water.

The *application of a bandage*, even though very cautiously made, is apt to induce gangrene. I have seen this happen when a roller was applied to the leg after ligature of the femoral artery, with the view of removing œdema.

Character.—The gangrene from ligature of an artery is almost invariably of the moist kind, as it usually arises from diminished *vis a tergo* and consequent stagnation of blood. The limb first becomes œdematous; vesications then form; and the skin assumes a purplish or greenish-black tint, rapidly extending up to the seat of operation. In some cases, though they are rare, simple mummification of the limb comes on; the skin assuming a dull yellowish-white hue, mottled by streaks that correspond to the veins, and becoming dry, horny, and shrivelled, about the extensor tendons of the instep.

Treatment.—Much may be done with the view of preventing gangrene. Thus, the limb should be slightly elevated, wrapped up loosely in cotton-wool, and laid on its outer side after the operation. If the weather be cold, hot-water bottles may be put into the bed, but *not in contact with the limb*. Should there be any appearance of stagnation of venous blood, the plan recommended by Guthrie of employing continuous and methodical friction in a direction upwards for twenty-four hours, so as to keep the superficial veins emptied, may be practised.

When mortification has fairly set in, amputation of the limb should be performed at once as the only chance of saving life, in all those cases in which the patient's constitutional powers are sufficiently strong to enable him to bear the shock of the operation. The limb should be removed at the seat of the original wound, or opposite the point at which the artery has been tied. In those cases, however, in which the gangrene follows injury of the femoral artery just below Poupart's ligament, Guthrie advises that the amputation should be done below the knee, where the gangrene usually stops. If the gangrene spread, with œdema or serous infiltration of the limb, the amputation should be done high up—at the shoulder-joint, or in the upper third of the thigh. In these cases a large number of vessels usually require ligature, having been enlarged by the collateral circulation.

CHAPTER XV.

TRAUMATIC ANEURISM AND ARTERIO-VEINOUS WOUNDS.

TRAUMATIC ANEURISM.

WE have hitherto discussed those wounds of arteries in which the blood is discharged freely from an open wound, but all cases are not so simple as these. It sometimes happens that there is a subcutaneous extravasation, forming a more or less distinct cavity, into which the blood is thrown from the wounded artery, accompanied usually by pulsation of the swelling, and occasionally by thrill and bruit. This extravasation constitutes a **Traumatic Aneurism**, and may arise in three ways: 1, The punctured wound leading to the injured artery may be oblique or indirect, and thus the blood may partly escape at the cutaneous opening, and partly be extravasated into the tissues around the vessel. 2, The puncture in the integuments may be closed by plaster, or a pad of lint and a bandage, and thus no blood may escape externally, although the wound in the artery remains patent, and blood is forced out into the substance of the part. 3, There may be no external wound, the artery being punctured or torn subcutaneously by the fragments of a fractured bone, by a violent strain, by the injury inflicted in a dislocation, or by the Surgeon in his efforts to reduce it.

Two forms of aneurism are described as arising from such injuries as the above: the diffused and the circumscribed.

DIFFUSED TRAUMATIC ANEURISM.—This consists of an effusion of blood from a wounded or ruptured artery, limited in extent by the resistance of the surrounding parts. In the immediate neighbourhood of the opening in the vessel there is an ill-defined cavity communicating with the artery formed by the separation of the surrounding parts by the pressure of the blood. There is no true sac, and such boundary as there may be is formed partly by coagulom, and partly by the surrounding fasciæ, muscles and other structures more or less matted together by inflammatory exudation. The extravasation continues to increase and to force its way amongst the tissues of the part until the resistance offered by the stretched and distended structures is equal to the pressure in the injured artery.

The effects of subcutaneous arterial hæmorrhage necessarily vary with the size of the artery, the nature of the wound, and the laxity of the surrounding parts. Thus, if the axillary artery be lacerated in the attempted reduction of an old dislocation of the shoulder-joint, the axilla, the loose tissue beneath the pectoral muscles and in the root of the neck, may be tensely distended with extravasated blood in a few minutes, while in a punctured wound of a deep-seated smaller vessel, such as the posterior tibial, many hours or even days may elapse before the extreme limit of distension of the surrounding parts has been reached. Many Surgeons, with much reason, object to the use of the word "aneurism" in connection with the more rapid arterial extravasations,

and no doubt such cases had better be described as "subcutaneous arterial hæmorrhages," but no sharp line can be drawn between them and the less perfectly circumscribed traumatic aneurisms.

Subcutaneous arterial hæmorrhage is indicated by the formation of a soft semi-fluctuating tumour often of very considerable size. If the opening be free and in a large artery the swelling increases rapidly, accompanied by the most intense tearing and throbbing pain, which may be at once relieved by pressure on the main trunk leading to the injured part. With this, in extreme cases, there may be the constitutional symptoms of loss of blood (p. 400). At first the skin covering the part is of natural colour, but as the pressure increases it may become congested and dusky. If the vessel be large there will at first be distinct pulsation in the tumour occasionally accompanied by a thrill and a distinct bruit, but these signs as a rule disappear as the tension of the distended parts becomes greater and the extravasated blood begins to coagulate. For this reason, unless the case is seen very early the diagnosis is often extremely difficult. If the hæmorrhage be from a small vessel or from a small punctured wound of a large vessel, and the surrounding parts be not lax, the swelling caused by the extravasation, after reaching a certain size somewhat rapidly, will increase more slowly so that some days may pass before a high degree of tension is developed. In whatever way arising, as soon as the tension becomes marked the pressure of the extravasated blood arrests the return of blood through the veins accompanying the artery, and in this way great œdema of the parts below the injury may be caused. Before much extravasation has taken place pulsation may be felt in the artery below the seat of injury unless the vessel be completely torn across or extensively injured, but most commonly this ceases when the pressure from extravasation becomes great. As soon as the extravasation reaches a sufficient size the tension it exerts on the surrounding tissues gives rise to all the phenomena of inflammation. The skin covering the swelling becomes hot, red, and œdematous. The red colour is often modified by the pigment from the extravasated red corpuscles, the various tints commonly seen in a bruise being mingled with the florid red of acute inflammation. Tenderness and acute throbbing pain are also present, and the temperature may rise to three or four degrees above the normal point; thus this condition may very closely resemble an acute abscess, and many cases are on record in which an incision has been made into the tumour under this supposition.

These cases if left alone rarely, if ever, undergo spontaneous cure. They either increase in size until the integument covering them sloughs and ruptures, or the external wound, which has been temporarily closed, gives way; or else they inflame and suppurate, pointing at last, like an abscess, and, on bursting, give rise to a sudden gush of blood, which may at once, or by its rapid recurrence, prove fatal. The combined obstruction to the flow through the artery and the pressure on the veins may cause gangrene of the limb at an early stage of the case. In some cases the temporary boundary of clotted blood and inflammatory exudation may give way, and the loss of blood extravasated into the areolar tissue beneath the fascia of the limb may be so great as to cause death from syncope.

Diagnosis.—Large subcutaneous arterial hæmorrhages, if seen early, are usually recognised without difficulty. The nature of the injury, the rapid swelling, possibly pulsating at first, the great tension and pain, the cessation

to allow of the temporary arrest of the bleeding by digital pressure below the carotid tubercle, this should be at once done. The wound must then be enlarged, and if possible, the artery tied above and below the bleeding point, parts of one or more of the transverse processes being removed, if necessary. Failing this, the Surgeon must resort to careful plugging of the wound, or he may be able to seize the bleeding vessel in forceps and leave them *in situ* for several days.

Traumatic Aneurism of the Vertebral Artery has been recorded in twenty cases by Matas, of which six recovered, one of these being a case of his own, in which the sac was freely laid open in the suboccipital region and the hæmorrhage successively arrested by plugging. This treatment would appear to give the best hope of success, if digital compression of the artery and direct pressure on the aneurism fail to produce a cure.

VESSELS OF THE TRUNK.

INTERNAL MAMMARY.—Wounds of this artery rarely come under treatment, as its course lies chiefly in front of the heart and great vessels, so that penetrating wounds implicating it are usually immediately fatal from injury to the parts beneath. The *treatment*, in case the patient escapes fatal injuries in deeper parts, is to tie the artery at the wounded spot, if necessary removing a costal cartilage in order to expose it. No other treatment is likely to arrest the bleeding, because of the free anastomoses with the intercostals.

INTERCOSTAL ARTERIES.—These are rarely wounded except in gunshot wounds or stabs fracturing a rib. The hæmorrhage is seldom severe; but should it require *treatment*, the lower border of the rib corresponding to the artery must be exposed by a free incision. On removing the fragments the bleeding artery may come into view, and can be twisted or tied; or it may be turned out of its groove by means of a periosteal elevator, and sufficiently exposed to be tied. If necessary, a piece of rib may be removed to lay bare the vessel more fully. As a temporary means, pressure can be applied thus:—A piece of linen is to be pushed through the wound into the pleural cavity, &c. as to form a pocket; inside a sufficient quantity of lint or tow is pushed into the pocket to make it too large to pass out by the intercostal space; it is then forcibly pulled upon by the part of the linen outside the chest-wall, and secured in position by a couple of pins pushed across on a level with the skin.

VESSELS OF THE UPPER LIMB.

SUBCLAVIAN ARTERY.—Wounds of the Subclavian Artery are almost invariably fatal; though, owing to the protection afforded by the clavicle, they rarely occur except from gunshot injuries or stabs. From the rapidly fatal nature of wounds of the subclavian artery, **Traumatic Aneurisms** in this situation are not met with; but where the artery passes into the axilla below the margin of the first rib, they are not unfrequent.

Aneurismal Varix. resulting from wound of the Subclavian Artery and has been seen, notwithstanding the separation that exists between the vessels throughout their whole extent. These injuries have likewise been the result of sword-thrusts, and do not admit of any surgical

AXILLARY ARTERY.—In **Open Wounds of the Axillary Artery and its Branches**, the rule of practice is to expose the bleeding vessel and tie it on each side of the wound. The branches of the artery are so numerous that there must always be some uncertainty, in a case of punctured wound, whether the main trunk or a branch is injured, even when the direction of the wound and the abundance of the bleeding would suggest the former. This doubt can be cleared up only by exposing the bleeding point, and in order to do this efficiently, it may sometimes be necessary to divide both the pectoral muscles across the line of their fibres.

In secondary hæmorrhage, the state of the parts may be such as to make it very difficult to expose the artery cleanly in the wound, and the temptation to apply a proximal ligature under these circumstances is very strong, but this should never be done before a thorough attempt has been made to tie the vessel at the bleeding point, by freely opening up the wound and enlarging it, if necessary. The anastomoses between the branches of the subclavian and the axillary are so free that ligature of the third part of the subclavian is extremely likely to fail. Ligature of the first part of the axillary artery would, in a case of secondary hæmorrhage, be just as difficult as exposing the bleeding point, and could be done after division of the pectoralis major and minor, should it be impossible to secure the vessel at the wounded point. In a case of secondary hæmorrhage, the ligature of the first part of the axillary by a curved incision below the clavicle, as described in Chap. XLIV., Vol. II., would be most difficult; as the axilla would probably be filled with extravasated blood, and the parts matted together by the inflammation and suppuration which caused the failure in the repair of the artery. In all cases of secondary hæmorrhage, it would be safer to expose the artery by an incision in the line of the vessel dividing the pectoral muscles. The subclavian must be tied above the clavicle only as a last resource. The operation has been attended with success enough to justify its adoption should other means fail. Of 15 cases in which it has been performed for hæmorrhage from wounds in the axilla or from stumps, I find that 9 were cured and 6 died.

Traumatic Aneurism in the Axilla may arise from gunshot wounds or stabs, or in some cases from subcutaneous rupture of the vessel. In the latter case the patient while straining his arm in a raised position feels a sudden snap, which is rapidly followed by a large extravasation of blood in the axilla, forming the so-called diffused traumatic aneurism.

There are more than 40 cases on record in which axillary aneurism has followed an injury to the vessel occurring during the reduction of a dislocation. In only a few of these has the dislocation been recent. Amongst these is one recorded by Warren in which the vessel was ruptured in consequence of the Surgeon using his foot in the axilla as a fulcrum, but without taking off his boot. In the great majority of cases the dislocation has been of old-standing, and considerable force has been used. Gibson has related three cases of rupture of the artery in the attempt to reduce such cases by the pulleys. Pelletan mentions a case in which the rapid swelling following the rupture of the artery was mistaken for emphysema from fractured ribs. An incision was made into it and the patient bled to death. These cases show the necessity for great caution in the use of powerful extending force in the reduction of old dislocations, when adhesions may have formed between the artery and the head of the bone.

Distinction must be clearly made between the diffused and circumscribed forms of traumatic aneurism of the axilla. In the *diffused variety* there is subcutaneous arterial extravasation, forming more or less rapidly a tumour of considerable size. The swelling presents none of the characteristic signs of an aneurism, and can be distinguished from an ordinary extravasation by the loss of the pulse at the wrist and the œdema of the arm. Some of these arterial extravasations in the axilla tend to diffuse themselves with great rapidity, extending under the pectoral muscles, and even up around the shoulder.

In all these cases there is great danger of suppuration and sloughing of the tissues into which the blood is extravasated, and gangrene of the limb itself may result.

In the *circumscribed form*, on the other hand, the swelling develops slowly, and presents the usual signs of aneurism, such as thrill and pulsation. Under these circumstances the disease may get well spontaneously, as happened in cases recorded by Van Swieten, Sabatier, and Hodgson. In other instances again, the disease has remained stationary for years, or has undergone consolidation under medical treatment. It cannot, however, be considered sound practice to leave a circumscribed traumatic aneurism of this artery without surgical interference, after the ordinary dietetic and hygienic plans of treatment have failed, for it may at any time become rapidly diffused, or inflame and suppurate.

The *Treatment* of traumatic axillary aneurism must depend on whether it be diffused or circumscribed.

In *subcutaneous arterial extravasation*—the so-called diffused traumatic aneurism—the plan of treatment recommended so strongly by Guthrie must always be followed, viz., to open up the axilla, turn out the coagula, and ligature the wounded artery. The treatment is the same whether the extravasation result from a punctured wound or a subcutaneous rupture of the vessel. The operation consists in compressing the subclavian above the clavicle, either by the pressure of the finger from the surface, or, as was done by Syme in his case, by previously making an incision over it, through which it could be more readily commanded; then laying the tumour open by a free incision through the anterior fold of the axilla and the pectoral muscles, turning out the coagula, and seeking for and ligaturing both ends of the artery: for it must be remembered that the distal extremity of the torn vessel will probably bleed freely, owing to the open anastomoses round the shoulder.

Should secondary hæmorrhage or gangrene follow the operation, amputation at the shoulder is the only plan that holds out a chance of life to the patient. The result of departing from this first principle of the treatment of diffused traumatic aneurism is well shown by three recorded cases in which the subclavian artery was tied for extravasation following subcutaneous rupture of the axillary artery. Two of the patients died of gangrene and secondary hæmorrhage, and in the successful case, secondary hæmorrhage occurred, gangrene of the arm threatened, and life was saved only by amputation at the shoulder-joint.

In the treatment of the *circumscribed variety* the same principle cannot guide us as in the management of the diffuse extravasation, for not only is the circumscribed aneurism provided with a sac, but the vessel at the point injured will very probably be found to have undergone changes that render it little able to bear the application of the ligature. It will be softened, thickened,

and lacerable, with perhaps a wide funnel-shaped aperture leading into the sac, which will be closely incorporated with the neighbouring parts. But, indeed, the treatment of this form of circumscribed traumatic aneurism by the ligature of the artery on the proximal side of the sac has been found to be attended with remarkable success. In eight recorded cases in which this operation was performed, not one fatal result was noted. In all, the aneurism arose from stabs or gunshot wounds, and had existed for various periods, ranging from two weeks to four years. In four of the cases the artery was ligatured above, and in four below the clavicle: and in one case of each category there was suppuration of the sac.

The particular point at which the artery should be ligatured must depend upon the condition of the tumour. If this be of large size, or arise from the upper part of the axillary artery above or immediately below the pectoralis minor muscle, there is no choice but to deligate the vessel above the clavicle. Should, however, the principal increase in the tumour take place in a direction downwards and forwards under the great pectoral muscle, the portion of the artery immediately below the clavicle not being covered by the sac, the question would arise whether this part might not be selected for the application of the ligature: and as the results of both operations have hitherto been equally favourable, this must rather be determined by the peculiarities in each case than on more general grounds. Most Surgeons, I think, would prefer ligaturing the artery above the clavicle, as being a simpler proceeding than tying it below that bone; the latter procedure, moreover, has the disadvantage of bringing the scalpel into very close proximity with the sac, which, were it to stretch upwards under the pectoralis minor to a greater extent than could be discernible externally, might possibly be opened by the knife, as has happened even in operating above the clavicle.

Compression of the artery on the distal side of the tumour succeeded in curing the disease in a case that was under Goldsmith of Vermont.

BRACHIAL ARTERY.—The hæmorrhage from **Wounds of the Brachial Artery** should be arrested by ligature on each side of the aperture.

This vessel may be punctured in venesection, an accident which was formerly of frequent occurrence when blood-letting was practised by professed phlebotomists: an abundant escape of blood will then occur while the thumb is still on the vein. Should the condition of the patient permit, and the necessary instruments and assistance be at hand, the Surgeon should expose the artery and apply a ligature above and below the wound, at the same time tying the wounded vein. Frequently, however, this treatment will be impracticable, and all that can be done will be to apply a graduated compress. If the patient recover from the disease for which he was bled and an aneurism form, it may be operated on at a later time.

In the **Circumscribed Traumatic Aneurism** at the bend of the arm, following a wound of the brachial artery, we have the usual soft or semi-solid pulsating tumour, which can readily be emptied by pressure, and is accompanied by more or less bruit. This disease may be treated in one of three ways: 1, by compression upon or above the tumour; 2, by ligaturing the artery leading to it; or 3, by cutting through the sac, and deligating the vessel on each side of the aperture in it.

Compression has been successfully carried out by means of a graduated compress on the tumour, and a ring-tourniquet on the artery higher up.

traumatic aneurism, communicating on one side with the artery, and on the other with the vein, which is always in a state of varix. A varicose aneurism is, in fact, a circumscribed traumatic aneurism *plus* an aneurismal varix. This is well represented in the annexed cuts, from drawings of Sir C. Bell's, in the museum of University College, representing a varicose aneurism before and after it had been opened (Figs. 151 to 154). In this case there appears to have been a high division of the brachial, and a communicating branch below the wound, between the radial and ulnar; in consequence of which, as

Fig. 152. — The same Tumour laid open, showing the Circumscribed False Aneurism between the two Vessels.

Mr. Shaw informed me, the tumour pulsated as forcibly after the artery had been tied as before, the blood finding its way back through the aneurism into the veins. Gangrene of the hand and arm followed.

Symptoms.—In the symptoms of varicose aneurism, we have a combination of the characters of aneurismal varix and of the circumscribed traumatic aneurism; there is a pulsating tumour, at first soft and compressible, but, after a time, becoming more solid, in consequence of the deposit of thrombus within it; superficial to this tumour, the vein is dilated into a fusiform pouch.

Fig. 154. — The opened Tumour removed from its Connections.

presenting the ordinary characters of varix. The sounds heard in these tumours are of two distinct kinds: there is the peculiar buzzing thrill that always exists where there is a communication between an artery and a vein; besides this there is a blowing or bellows sound, caused by the aneurism. These signs are most perceptible when the limb is in a dependent position, and the sounds can often be heard in the veins at a considerable distance from the seat of injury. There is also some impairment in the nutrition and temperature of the parts supplied by the injured vessels. As the disease advances,

the vein is due to abnormal blood-pressure from the direct entry of arterial blood into it.

The **Symptoms** consist of a tumour at the seat of injury, which can be emptied by pressure upon the artery leading to it, or by compressing its walls. If subcutaneous, this tumour is of a blue or purple colour, of an oblong shape, and will be seen to receive the dilated and tortuous veins. It will be found to pulsate distinctly with a tremulous jarring motion, rather than a distinct impulse. Auscultation detects in it a loud and blowing, whiffing, rasping, or hissing sound, usually of a peculiarly harsh character. This sound has very

Fig. 151.—A Varicose Aneurism at the Bend of the Arm unopened.

aptly been compared by Porter to the noise made by a fly in a paper-bag, and by Liston to the sound of distant and complicated machinery. The thrill and sound are more distinct in the upper than in the lower part of the limb, and are most perceptible if the limb be allowed to hang down so as to become congested. Besides these local symptoms, there is usually some muscular weakness, together with diminution in the temperature of the part supplied by the injured artery.

Treatment.—As this condition, when once established, is stationary, all

Fig. 152.—The same Varicose Aneurism removed from its connections.

operative interference should be avoided, an elastic bandage merely being applied. Should a case occur in which more than this is required, the artery must be cut down upon and ligatured on each side of the wound in it. Holmes suggests that in aneurismal varix a cure might possibly be obtained by pressure directed solely to the orifice in the vein.

VARICOSE ANEURISM.—In this condition the openings in the artery and vein do not directly communicate (see Figs. 152 and 153), but an aneurismal sac is formed between the two vessels, through which the blood passes into the vein.

The **Pathological Condition** consists in the formation of a circumscribed

CHAPTER XVI.

WOUNDS OF SPECIAL BLOOD-VESSELS.*

VESSELS OF THE HEAD AND NECK.

CAROTID ARTERY.—**Wounds of the Carotid Artery** and of its branches are not uncommon in civil practice, as the neck is frequently the seat of suicidal wounds. The hæmorrhage from wounds of the main trunk is usually immediately fatal. In the event of a Surgeon being at hand, both ends of the bleeding vessel must be ligatured. Should the jugular vein be also wounded a ligature must be applied above and below the opening, but if the wound be very small—a mere puncture—it may be closed by pinching it up and applying the ligature in such a way as not completely to occlude the vessel. Should the hæmorrhage, whether primary or secondary, proceed from a deep branch of the external carotid, as the internal maxillary, so situated as not to admit of the vessel being ligatured at the seat of wound, the ordinary rule of tying a wounded artery at the seat of injury must be departed from, and the main trunk must be ligatured at the most convenient spot. Considerable difference of opinion has existed as to whether, under these circumstances, it is better to tie the external or the common carotid. Guthrie strongly advocated the application of the ligature to the external carotid, but most Surgeons have preferred to tie the common trunk above the omohyoid, fearing that the application of a ligature amongst the numerous branches of the external carotid would be followed by secondary hæmorrhage. The results of this mode of treatment, however, have been far from satisfactory; not only have many patients died directly from the operation itself, but in a very large proportion the hæmorrhage for which it was performed has recurred and proved fatal. Harrison Cripps has collected 50 cases of ligature of the common trunk for hæmorrhage, 28 of which terminated fatally. He has therefore advocated a return to Guthrie's practice of applying the ligature to the external carotid, and the exact point he recommends is *between the superior thyroid and the larynx*. Wyeth recommends simultaneous ligature of the superior thyroid. This operation is not difficult of performance, and seems in itself to be less dangerous than the deligation of the main trunk. Madelung has collected the records of 60 cases, of which only 7 died. There seems every reason therefore for preferring it, when possible, to the more serious operation of tying the common trunk.

INTERNAL CAROTID.—If the internal carotid is wounded, ligature of the common carotid gives the best chance of recovery.

In consequence of the speedy fatality of the wounds of the carotid artery and its branches, **Traumatic Aneurisms** are rarely met with in this situation; they do, however, occasionally occur, and the records of surgery contain

* A full description of the operations required for the ligature of the various arteries will be found in Vol. II. Chapters XLIII. and XLIV.

at least six instances of the kind, in each of which the common carotid was tied, and the patient ultimately recovered.

Aneurismal Varix in the Neck, dependent on puncture of the **Internal Jugular Vein and Carotid Artery**, usually the result of sword-thrusts, is apparently of more frequent occurrence than traumatic aneurism in this region: probably owing to the close proximity of the vein rendering it difficult for the artery to be wounded on the outer or anterior sides, without that vessel being first perforated. The symptoms offer the general characteristics of aneurismal varix, but have several points that are worthy of special remark.

The wound of the vessels has been in every instance followed by the effusion of a large quantity of blood into the loose areolar tissue of the neck; the extravasation acquiring even the size of a child's head, and threatening immediate suffocation. As this extravasation subsided, the ordinary characters of aneurismal varix began to manifest themselves. The period at which these symptoms first made their appearance varied somewhat in the different cases, but they always occurred within four or five days of the receipt of the injury. In none of the cases did the disease appear to shorten life, or to occasion any dangerous or inconvenient effects, with the exception of some difficulty in lying on the affected side, and occasional giddiness or noise in the head on stooping. No operation is admissible in these affections.

Varicose Aneurism of the internal jugular and carotid artery is rare. Playette has collected 16 cases, all of which tended to amelioration or spontaneous cure. Three cases were operated upon; two of these died, and the third was not improved.

TEMPORAL ARTERY.—**Traumatic Aneurism of the Temporal Artery**, and of its branches, has occasionally occurred as the result of partial division of these vessels in cupping on the temple. I have met with two cases of this kind, in both of which the disease was readily cured by laying the tumour open, turning out its contents, and tying the artery on each side of it.

INTERNAL MAXILLARY.—This artery is occasionally injured and wounded in gunshot wounds. If the hæmorrhage be too copious to be restrained by hot water, cold or styptics, the external or common carotid must be tied.

LINGUAL ARTERY.—This vessel is occasionally injured in gunshot wounds. If the bleeding point cannot be seized by forcipressure-forceps from the mouth and the Surgeon can be perfectly certain that the blood is coming from the lingual, he may tie that vessel above the hyoid bone (see Diseases of the Tongue), otherwise it is better to ligature the external or common carotid—the external for choice.

VERTEBRAL ARTERY.—**Wounds of the Vertebral Artery** occasionally occur as the result of stabs or gunshot wounds in the neck. In these wounds there is a danger of mistaking the source of the hæmorrhage, as pressure on the carotid, if made below the transverse process of the sixth cervical vertebra, arrests the flow of blood in the vertebral as well, which, up to this point, lies immediately beneath it. This transverse process is at least two inches above the clavicle, and lies much higher than one is apt to think. There are no fewer than sixteen cases on record in which the carotid has been tied for a wound of the vertebral, in consequence of this mistake. Of nineteen cases of wound of the vertebral collected by Matas, only two recovered, and in both the hæmorrhage was arrested by plugging the wound, the plugs in one case being dipped in a styptic solution. If the wound of the vessel be sufficiently high

to allow of the temporary arrest of the bleeding by digital pressure below the carotid tubercle, this should be at once done. The wound must then be enlarged, and if possible, the artery tied above and below the bleeding point parts of one or more of the transverse processes being removed, if necessary. Failing this, the Surgeon must resort to careful plugging of the wound, or he may be able to seize the bleeding vessel in forceps-pressure-forceps and leave them *in situ* for several days.

Traumatic Aneurism of the Vertebral Artery has been recorded in twenty cases by Matsui, of which six recovered, one of these being a case of his own, in which the sac was freely laid open in the suboccipital region and the hemorrhage successively arrested by plugging. This treatment would appear to give the best hope of success, if digital compression of the artery and direct pressure on the aneurism fail to produce a cure.

VESSELS OF THE TRUNK.

INTERNAL MAMMARY.—Wounds of this artery rarely come under treatment, as its course lies chiefly in front of the heart and great vessels, so that penetrating wounds implicating it are usually immediately fatal from injury to the parts beneath. The *treatment*, in case the patient escapes fatal injuries to deeper parts, is to tie the artery at the wounded spot, if necessary removing a costal cartilage in order to expose it. No other treatment is likely to arrest the bleeding, because of the free anastomoses with the intercostals.

INTERCOSTAL ARTERIES.—These are rarely wounded except in gunshot wounds or stabs fracturing a rib. The hemorrhage is seldom severe; but should it require *treatment*, the lower border of the rib corresponding to the artery must be exposed by a free incision. On removing the fragments the bleeding artery may come into view, and can be twisted or tied; or it may be turned out of its groove by means of a periosteal elevator, and sufficiently exposed to be tied. If necessary, a piece of rib may be removed to lay bare the vessel more fully. As a temporary means, pressure can be applied thus:—A piece of linen is to be pushed through the wound into the pleural cavity, so as to form a pocket; inside a sufficient quantity of lint or tow is pushed into the pocket to make it too large to pass out by the intercostal space; it is then forcibly pulled upon by the part of the linen outside the chest-wall, and secured in position by a couple of pins pushed across on a level with the skin.

VESSELS OF THE UPPER LIMB.

SUBCLAVIAN ARTERY.—Wounds of the **Subclavian Artery** are almost invariably fatal; though, owing to the protection afforded by the clavicle, they rarely occur except from gunshot injuries or stabs. From the rapidly fatal nature of wounds of the subclavian artery, **Traumatic Aneurisms** in this situation are not met with; but where the artery passes into the axilla below the margin of the first rib, they are not unfrequent.

Aneurismal Varix, resulting from wound of the *Subclavian Artery and Vein*, has been seen, notwithstanding the separation that exists between the two vessels throughout their whole extent. These injuries have likewise usually been the result of sword-thrusts, and do not admit of any surgical interference.

AXILLARY ARTERY.—In **Open Wounds of the Axillary Artery and its Branches**, the rule of practice is to expose the bleeding vessel and tie it on each side of the wound. The branches of the artery are so numerous that there must always be some uncertainty, in a case of punctured wound, whether the main trunk or a branch is injured, even when the direction of the wound and the abundance of the bleeding would suggest the former. This doubt can be cleared up only by exposing the bleeding point, and in order to do this efficiently, it may sometimes be necessary to divide both the pectoral muscles across the line of their fibres.

In secondary hæmorrhage, the state of the parts may be such as to make it very difficult to expose the artery cleanly in the wound, and the temptation to apply a proximal ligature under these circumstances is very strong, but this should never be done before a thorough attempt has been made to tie the vessel at the bleeding point, by freely opening up the wound and enlarging it, if necessary. The anastomoses between the branches of the subclavian and the axillary are so free that ligature of the third part of the subclavian is extremely likely to fail. Ligature of the first part of the axillary artery would, in a case of secondary hæmorrhage, be just as difficult as exposing the bleeding point, and could be done after division of the pectoralis major and minor, should it be impossible to secure the vessel at the wounded point. In a case of secondary hæmorrhage, the ligature of the first part of the axillary by a curved incision below the clavicle, as described in Chap. XLIV., Vol. II., would be most difficult: as the axilla would probably be filled with extravasated blood, and the parts matted together by the inflammation and suppuration which caused the failure in the repair of the artery. In all cases of secondary hæmorrhage, it would be safer to expose the artery by an incision in the line of the vessel dividing the pectoral muscles. The subclavian must be tied above the clavicle only as a last resource. The operation has been attended with success enough to justify its adoption should other means fail. Of 15 cases in which it has been performed for hæmorrhage from wounds in the axilla or from stumps, I find that 9 were cured and 6 died.

Traumatic Aneurism in the Axilla may arise from gunshot wounds or stabs, or in some cases from subcutaneous rupture of the vessel. In the latter case the patient while straining his arm in a raised position feels a sudden snap, which is rapidly followed by a large extravasation of blood in the axilla, forming the so-called diffused traumatic aneurism.

There are more than 40 cases on record in which axillary aneurism has followed an injury to the vessel occurring during the reduction of a dislocation. In only a few of these has the dislocation been recent. Amongst these is one recorded by Warren in which the vessel was ruptured in consequence of the Surgeon using his foot in the axilla as a fulcrum, but without taking off his boot. In the great majority of cases the dislocation has been of old-standing, and considerable force has been used. Gibson has related three cases of rupture of the artery in the attempt to reduce such cases by the pulleys. Pelletan mentions a case in which the rapid swelling following the rupture of the artery was mistaken for emphysema from fractured ribs. An incision was made into it and the patient bled to death. These cases show the necessity for great caution in the use of powerful extending force in the reduction of old dislocations, when adhesions may have formed between the artery and the head of the bone.

to allow of the temporary arrest of the bleeding by digital pressure below the carotid tubercle, this should be at once done. The wound must then be enlarged, and if possible, the artery tied above and below the bleeding point, parts of one or more of the transverse processes being removed, if necessary. Failing this, the Surgeon must resort to careful plugging of the wound, or he may be able to seize the bleeding vessel in forcipressure-forceps and leave them *in situ* for several days.

Traumatic Aneurism of the Vertebral Artery has been recorded in twenty cases by Matas, of which six recovered, one of these being a case of his own, in which the sac was freely laid open in the suboccipital region and the hæmorrhage successively arrested by plugging. This treatment would appear to give the best hope of success, if digital compression of the artery and direct pressure on the aneurism fail to produce a cure.

VESSELS OF THE TRUNK.

INTERNAL MAMMARY.—Wounds of this artery rarely come under treatment, as its course lies chiefly in front of the heart and great vessels, so that penetrating wounds implicating it are usually immediately fatal from injury to the parts beneath. The *treatment*, in case the patient escapes fatal injuries to deeper parts, is to tie the artery at the wounded spot, if necessary removing a costal cartilage in order to expose it. No other treatment is likely to arrest the bleeding, because of the free anastomoses with the intercostals.

INTERCOSTAL ARTERIES.—These are rarely wounded except in gunshot wounds or stabs fracturing a rib. The hæmorrhage is seldom severe; but should it require *treatment*, the lower border of the rib corresponding to the artery must be exposed by a free incision. On removing the fragments the bleeding artery may come into view, and can be twisted or tied; or it may be turned out of its groove by means of a periosteal elevator, and sufficiently exposed to be tied. If necessary, a piece of rib may be removed to lay bare the vessel more fully. As a temporary means, pressure can be applied thus:—A piece of linen is to be pushed through the wound into the pleural cavity, so as to form a pocket; inside a sufficient quantity of lint or tow is pushed into the pocket to make it too large to pass out by the intercostal space; it is then forcibly pulled upon by the part of the linen outside the chest-walls, and secured in position by a couple of pins pushed across on a level with the skin.

VESSELS OF THE UPPER LIMB.

SUBCLAVIAN ARTERY.—Wounds of the **Subclavian Artery** are almost invariably fatal; though, owing to the protection afforded by the clavicle, they rarely occur except from gunshot injuries or stabs. From the rapidly fatal nature of wounds of the subclavian artery, **Traumatic Aneurisms** in this situation are not met with; but where the artery passes into the axilla below the margin of the first rib, they are not unfrequent.

Aneurismal Varix, resulting from wound of the *Subclavian Artery and Vein*, has been seen, notwithstanding the separation that exists between the two vessels throughout their whole extent. These injuries have likewise usually been the result of sword-thrusts, and do not admit of any surgical interference.

and lacerable, with perhaps a wide funnel-shaped aperture leading into the sac, which will be closely incorporated with the neighbouring parts. But, indeed, the treatment of this form of circumscribed traumatic aneurism by the ligature of the artery on the proximal side of the sac has been found to be attended with remarkable success. In eight recorded cases in which this operation was performed, not one fatal result was noted. In all, the aneurism arose from stab or gunshot wounds, and had existed for various periods, ranging from two weeks to four years. In four of the cases the artery was ligatured above, and in four below the clavicle: and in one case of each category there was suppuration of the sac.

The particular point at which the artery should be ligatured must depend upon the condition of the tumour. If this be of large size, or arise from the upper part of the axillary artery above or immediately below the pectoralis minor muscle, there is no choice but to deligate the vessel above the clavicle. Should, however, the principal increase in the tumour take place in a direction downwards and forwards under the great pectoral muscle, the portion of the artery immediately below the clavicle not being covered by the sac, the question would arise whether this part might not be selected for the application of the ligature; and as the results of both operations have hitherto been equally favourable, this must rather be determined by the peculiarities in each case than on more general grounds. Most Surgeons, I think, would prefer ligaturing the artery above the clavicle, as being a simpler proceeding than tying it below that bone; the latter procedure, moreover, has the disadvantage of bringing the scalpel into very close proximity with the sac, which, were it to stretch upwards under the pectoralis minor to a greater extent than could be discernible externally, might possibly be opened by the knife, as has happened even in operating above the clavicle.

Compression of the artery on the distal side of the tumour succeeded in curing the disease in a case that was under Goldsmith of Vermont.

BRACHIAL ARTERY.—The hemorrhage from **Wounds of the Brachial Artery** should be arrested by ligature on each side of the aperture.

This vessel may be punctured in venesection, an accident which was formerly of frequent occurrence when blood-letting was practised by professed phlebotomists: an abundant escape of blood will then occur while the thumb is still on the vein. Should the condition of the patient permit, and the necessary instruments and assistance be at hand, the Surgeon should expose the artery and apply a ligature above and below the wound, at the same time tying the wounded vein. Frequently, however, this treatment will be impracticable, and all that can be done will be to apply a graduated compress. If the patient recover from the disease for which he was bled and an aneurism form, it may be operated on at a later time.

In the **Circumscribed Traumatic Aneurism** at the bend of the arm, following a wound of the brachial artery, we have the usual soft or semi-solid pulsating tumour, which can readily be emptied by pressure, and is accompanied by more or less bruit. This disease may be treated in one of three ways: 1, by compression upon or above the tumour; 2, by ligaturing the artery leading to it; or 3, by cutting through the sac, and deligating the vessel on each side of the aperture in it.

Compression has been successfully carried out by means of a graduated compress on the tumour, and a ring-tourniquet on the artery higher up.

Distinction must be clearly made between the diffused and circumscribed forms of traumatic aneurism of the axilla. In the *diffused variety* there is subcutaneous arterial extravasation, forming more or less rapidly a tumour of considerable size. The swelling presents none of the characteristic signs of an aneurism, and can be distinguished from an ordinary extravasation by the loss of the pulse at the wrist and the œdema of the arm. Some of these arterial extravasations in the axilla tend to diffuse themselves with great rapidity, extending under the pectoral muscles, and even up around the shoulder.

In all these cases there is great danger of suppuration and sloughing of the tissues into which the blood is extravasated, and gangrene of the limb itself may result.

In the *circumscribed form*, on the other hand, the swelling develops slowly, and presents the usual signs of aneurism, such as thrill and pulsation. Under these circumstances the disease may get well spontaneously, as happened in cases recorded by Van Swieten, Sabatier, and Hodgson. In other instances again, the disease has remained stationary for years, or has undergone consolidation under medical treatment. It cannot, however, be considered sound practice to leave a circumscribed traumatic aneurism of this artery without surgical interference, after the ordinary dietetic and hygienic plans of treatment have failed, for it may at any time become rapidly diffused, or inflame and suppurate.

The *Treatment* of traumatic axillary aneurism must depend on whether it be diffused or circumscribed.

In *subcutaneous arterial extravasation*—the so-called diffused traumatic aneurism—the plan of treatment recommended so strongly by Guthrie must always be followed, viz., to open up the axilla, turn out the coagula, and ligature the wounded artery. The treatment is the same whether the extravasation result from a punctured wound or a subcutaneous rupture of the vessel. The operation consists in compressing the subclavian above the clavicle, either by the pressure of the finger from the surface, or, as was done by Syme in his case, by previously making an incision over it, through which it could be more readily commanded; then laying the tumour open by a free incision through the anterior fold of the axilla and the pectoral muscles, turning out the coagula, and seeking for and ligaturing both ends of the artery: for it must be remembered that the distal extremity of the torn vessel will probably bleed freely, owing to the open anastomoses round the shoulder.

Should secondary hæmorrhage or gangrene follow the operation, amputation at the shoulder is the only plan that holds out a chance of life to the patient. The result of departing from this first principle of the treatment of diffused traumatic aneurism is well shown by three recorded cases in which the subclavian artery was tied for extravasation following subcutaneous rupture of the axillary artery. Two of the patients died of gangrene and secondary hæmorrhage, and in the successful case, secondary hæmorrhage occurred, gangrene of the arm threatened, and life was saved only by amputation at the shoulder-joint.

In the treatment of the *circumscribed variety* the same principle cannot guide us as in the management of the diffuse extravasation, for not only is the circumscribed aneurism provided with a sac, but the vessel at the point injured will very probably be found to have undergone changes that render it little able to bear the application of the ligature. It will be softened, thickened,

and lacerable, with perhaps a wide funnel-shaped aperture leading into the sac, which will be closely incorporated with the neighbouring parts. But, indeed, the treatment of this form of circumscribed traumatic aneurism by the ligature of the artery on the proximal side of the sac has been found to be attended with remarkable success. In eight recorded cases in which this operation was performed, not one fatal result was noted. In all, the aneurism arose from stabs or gunshot wounds, and had existed for various periods, ranging from two weeks to four years. In four of the cases the artery was ligatured above, and in four below the clavicle: and in one case of each category there was suppuration of the sac.

The particular point at which the artery should be ligatured must depend upon the condition of the tumour. If this be of large size, or arise from the upper part of the axillary artery above or immediately below the pectoralis minor muscle, there is no choice but to deligate the vessel above the clavicle. Should, however, the principal increase in the tumour take place in a direction downwards and forwards under the great pectoral muscle, the portion of the artery immediately below the clavicle not being covered by the sac, the question would arise whether this part might not be selected for the application of the ligature; and as the results of both operations have hitherto been equally favourable, this must rather be determined by the peculiarities in each case than on more general grounds. Most Surgeons, I think, would prefer ligaturing the artery above the clavicle, as being a simpler proceeding than tying it below that bone; the latter procedure, moreover, has the disadvantage of bringing the scalpel into very close proximity with the sac, which, were it to stretch upwards under the pectoralis minor to a greater extent than could be discernible externally, might possibly be opened by the knife, as has happened even in operating above the clavicle.

Compression of the artery on the distal side of the tumour succeeded in curing the disease in a case that was under Goldsmith of Vermont.

BRACHIAL ARTERY.—The hæmorrhage from **Wounds of the Brachial Artery** should be arrested by ligature on each side of the aperture.

This vessel may be punctured in venesection, an accident which was formerly of frequent occurrence when blood-letting was practised by professed phlebotomists; an abundant escape of blood will then occur while the thumb is still on the vein. Should the condition of the patient permit, and the necessary instruments and assistance be at hand, the Surgeon should expose the artery and apply a ligature above and below the wound, at the same time tying the wounded vein. Frequently, however, this treatment will be impracticable, and all that can be done will be to apply a graduated compress. If the patient recover from the disease for which he was bled and an aneurism form, it may be operated on at a later time.

In the **Circumscribed Traumatic Aneurism** at the bend of the arm, following a wound of the brachial artery, we have the usual soft or semi-solid pulsating tumour, which can readily be emptied by pressure, and is accompanied by more or less bruit. This disease may be treated in one of three ways: 1, by compression upon or above the tumour; 2, by ligaturing the artery leading to it; or 3, by cutting through the sac, and deligating the vessel on each side of the aperture in it.

Compression has been successfully carried out by means of a graduated compress on the tumour, and a ring-tourniquet on the artery higher up.

Great care must be taken not to induce sloughing of the tissues over the tumour by too forcible pressure. The limb should be carefully bandaged and maintained in the semi-flexed position. Should this plan not succeed, we must be guided by the conditions of the case. If the tumour be of recent origin, soft and compressible, or, though of longer duration, large, with a thin sac, and in danger of becoming diffused, it should be treated by direct incision, and the artery deligated on each side of the wound. Should the tumour be small, or of but moderate size, and the sac be tolerably thick and firm, it has been recommended to treat it by deligation of the brachial artery, either in the middle of the arm, or, as Anel did with success, immediately above the tumour. This mode of treatment is not, however, certainly followed by curing owing to the freedom of the anastomoses about the elbow. I have known it to fail in a case in which the sac was large and thin, the pulsations returning in a few days and the tumour continuing to enlarge. It is better, therefore, in all cases, if pressure fails, at once to have recourse to incision of the sac. With efficient antiseptic treatment the operation is not more dangerous than ligature at a distance.

Varicose Aneurism, at the bend of the arm, presents the ordinary characters of the disease. Occasionally, though rarely, it would appear that the aperture of communication between the aneurismal sac and the vein becomes closed, and thus the varicose is converted into the ordinary circumscribed traumatic aneurism.

The *Treatment* of this affection must be conducted on different principles from that of the ordinary circumscribed variety; for whatever be the density of the sac, it is never, as has already been explained (p. 472), a perfect one, having always an opening into the vein which would prevent its proper closure by the deposit of laminated fibrin. Of four cases related by Sabatier, which were treated by Anel's operation, amputation became necessary in two; and, in the other cases, the operation by incision of the sac was required before a cure could be effected. The sac must therefore be laid open, and the vessel tied on each side of it in the way that has been recommended in the treatment of varicose aneurism, and with the caution there laid down. If the varicose aneurism be converted, after a few days, into the circumscribed form, by the aperture into the vein becoming occluded, the treatment above recommended should be adopted.

In **Aneurismal Varix** of the arm, a roller and compress are all that can be required.

VESSELS OF THE FOREARM AND PALM.—**Wounds of the Arteries of the Forearm** are very commonly caused by pieces of glass or earthenware, or by knives. In every case the bleeding point must be cut down upon, and both ends of the vessel tied. This rule is peculiarly imperative in this situation, on account of the freedom of the anastomoses through the palmar arches. In many of these cases the bleeding is at first very free, but, being arrested by pressure, does not break out again until eight or ten days have elapsed: when, the arm being much infiltrated with blood, inflamed, and swollen, double ligature of the vessel at the seat of injury has to be practised under somewhat difficult and unfavourable circumstances.

Traumatic Aneurism of the Radial and Ulnar Arteries usually assumes the circumscribed form, owing to the pressure employed at the time of injury confining the extravasation. If it be small and recent, and situated

superficially at the lower part of the forearm, or if it be in any way diffused, the better plan is to cut down upon and through the tumour at once, ligaturing the vessel on each side. If, however, the aneurism be deeply seated amongst the mass of muscles at the upper part of the forearm, near the elbow-joint, the wound having healed, and the soft parts covering it being healthy and firm, compression of the brachial, with moderate pressure on the tumour itself, should first be tried, as it has been known to effect a cure. The application of Esmarch's bandage or forcible flexion of the elbow might possibly succeed if simple pressure failed.

If these means fail Liston advised ligature of the brachial artery, but as a rule it is better to open the sac and tie the vessel above and below the opening, as the freedom of the anastomoses round the elbow might cause failure of the treatment by proximal ligature. If the incisions be well planned and efficient antiseptic treatment adopted there is little danger of causing any permanent damage to the limb.

In a case of traumatic aneurism of the radial, just above the wrist, that came under my care, the sac had twice been laid open: the upper end of the radial had been tied: but attempts made to secure the distal end of the artery had been ineffectual, the result being a return of the aneurism, though in a small and more circumscribed form. This I cured by the application of pressure, by means of a small screw-tourniquet attached to a splint, to the radial artery where it lies between the extensor tendons of the thumb, the recurrent aneurism in this case being entirely fed by blood brought to its distal side through the deep palmar arch.

Wounds of the Palmar Arches not unfrequently occur from the breaking of glass or china in the hand, or stabs from some pointed instrument, and are always troublesome to manage. If the Surgeon sees the case shortly after the infliction of the wound, he may endeavour, by carefully enlarging the aperture, with due attention to the tendons and nerves, to reach the bleeding vessel. If the *superficial arch* be wounded, no difficulty will be found in securing it, but if it be the deep, he is very likely to fail. In some cases the artery can be seized in a pair of forcepressure-forceps, which may be left in the wound for twenty-four hours and then carefully removed. Under any circumstances, no effort should be spared to secure the vessel without using the graduated compress. One of the chief dangers of incisions into the palm of the hand is the occurrence of suppuration, extending to the synovial sheaths of the flexor tendons. It is therefore very important that such wounds should be treated antiseptically, well drained, and preserved from every source of irritation. A graduated compress by its pressure causes considerable irritation, and interferes with drainage. Moreover, if a compress is applied with sufficient force to stop the flow of blood through the artery, it must necessarily render the whole area it presses on bloodless. If, therefore, a compress be applied efficiently, and kept on, as is sometimes recommended, for three or four days, it must inevitably cause gangrene of the tissues with which it has been in contact: or, supposing the tissues are not quite dead, acute inflammation will set in as soon as the blood is admitted to them. This has but too often been the experience of Surgeons after the use of the compress; when it has been removed, a foul sloughing wound has been brought into view, with diffuse inflammation spreading round it. Under these circumstances secondary hæmorrhage is very likely to occur.

Still, if all other means fail, the Surgeon must fall back on the graduated compress, which, if well and firmly applied, will often succeed in arresting the bleeding. The proper mode of putting on this compress is as follows:—A tourniquet having been placed on the brachial artery, the whole hand and the wound must be thoroughly cleansed with 1 in 20 carbolic acid lotion. A wooden splint is then to be put on the back of the hand and the lower part of the forearm. The pad must be thickened at its lower end so as slightly to flex the fingers, thus relaxing the palmar fascia. A firm well-made graduated compress of antiseptic gauze or boric lint is now to be applied accurately with the apex downwards to the wound, and securely bandaged against it by a separate bandage. The patient should then be put to bed with the hand elevated. At the end of twelve to eighteen hours the bandage may be carefully removed without disturbing the splint or the compress, and re-applied with just sufficient force to keep the compress in position sticking to the wound without pressing strongly enough to empty the tissues beneath of blood. The patient should be kept for two days in the recumbent position with the hand elevated. It is sometimes recommended that the circulation through the limb should be controlled by a ring-tourniquet, applied on that artery above the wrist which appears most to correspond with the arch wounded, or better still, on the brachial itself; or the elbow may be forcibly flexed, and the forearm bandaged to the arm in this position, so that the hand rests upon the shoulder. These precautions are, however, unnecessary, if the compress is properly applied; but they may sometimes be made use of with advantage after the bandage has been relaxed. The compress, after pressure has been relaxed, may be left undisturbed for five or six days, unless there be redness, swelling, and pain, indicating the formation of pus beneath it, when the sooner it is taken off the better. Should the wound be found healing and looking well, there need be no fear of further hæmorrhage; but should the palm be sloughy and infiltrated, there will be a considerable risk of the bleeding recurring. Under these circumstances, it is useless again to resort to compression, and other means must be employed.

Should an ineffectual attempt have been made to arrest the primary hæmorrhage, or should the case not be seen until several days have elapsed, when secondary hæmorrhage has occurred, and the palm has become infiltrated and swollen, pressure can no longer be borne upon the seat of injury, and it may be almost impracticable to endeavour to search for the injured vessel in the midst of sloughy and infiltrated tissues. By applying a tourniquet to the arm, and carefully enlarging the wound and scraping away the sloughy tissue with a sharp spoon, the bleeding vessel has, however, been ligatured successfully in some cases. Failing this, it is necessary to deviate from the ordinary rule of practice, and the operation of proximal ligature may be performed. The Surgeon may either tie both arteries above the wrist, or at once delegate the brachial. Both methods of treatment have their advocates. I prefer the simultaneous ligature of the two arteries of the forearm, just above the wrist, where they are superficial and very easily reached. In several cases under my care, the radial and ulnar, immediately above the hand, have been tied at the same time with complete success, and I have never seen a case in which this operation has failed: but could hæmorrhage occur after it, as might happen in the case of an enlarged

median or interosseous artery, the Surgeon must have recourse to compression or ligature of the brachial.

Circumscribed Traumatic Aneurism in the Palm is by no means of frequent occurrence. It may, however, follow wounds of the palmar arches. In such a case as this, forcible flexion of the elbow or the application of Esmarch's bandage might be tried. If these fail it would clearly be out of the question to lay open the sac, and to search for the injured vessel in the midst of the aponeurotic and tendinous structures of the hand. It would consequently be necessary, either to tie the radial and ulnar arteries immediately above the wrist, or to ligature the brachial in the middle of the arm. The latter plan should be preferred; as, were the first mode of treatment put into practice, the sac might continue to be fed by the interosseous artery, as happened in a case of Roux's, in which the patient died of hæmorrhage from the palmar aneurism after ligature of both arteries of the forearm. In the case represented (Fig. 150) Liston successfully ligatured the brachial in the mid-arm, after compression upon it had failed to effect a cure.

VESSELS OF THE LOWER LIMB.

GLUTEAL ARTERY.—**Traumatic Aneurisms of the Gluteal Artery** are of less frequent occurrence than might *a priori* have been imagined, from the situation of the vessel exposing it to injury. These aneurisms may acquire an enormous size, and are often accompanied by much redness and cedema of the skin covering them. Pulsation may be indistinct or absent, and thus such cases may closely resemble large abscesses and have been more than once mistaken for them. In John Bell's celebrated case, the tumour is said to have been of "prodigious size," and to have contained eight pounds of blood. In Syme's case the tumour was as large at the base as a man's head, occupied the whole hip, and rose into a blunt cone.

The *Treatment* that should be adopted is to compress the aorta by means of the aortic tourniquet; then to lay open the tumour freely, turn out its contents, and pass a ligature by means of an aneurism-needle round the short trunk of the gluteal as it emerges from the pelvis.

EXTERNAL ILIAC ARTERY.—Wounds of this vessel must almost invariably be fatal. If, however, the bleeding has been temporarily controlled by pressure, an aortic tourniquet should be applied, the wound enlarged and the vessel ligatured above and below the puncture.

In a case of **Circumscribed Traumatic Aneurism** following a wound with a pocket-knife, Clutton successively ligatured the external iliac artery above and below the sac.

FEMORAL ARTERY.—The hæmorrhage from the **Femoral Artery, Common, Superficial or Deep**, when wounded is always very profuse. In all cases, ligature of the vessel at the seat of injury should be practised.

If a **Diffused Traumatic Aneurism** have already formed, the artery should be commanded by a tourniquet or by pressure on the aorta, the sac laid open, and the bleeding vessel tied. Guthrie has collected a great number of cases, which prove incontestably that the general principles of treatment of wounded arteries must not be departed from, when the arteries of the groin or thigh are wounded. On the contrary, the facility with which in most cases the circulation is kept up, and the readiness with which secondary hæmorrhage

comes on as a consequence of the free anastomoses in this situation, render the rule of applying a ligature on each side of the wound peculiarly stringent in all such cases. Secondary hæmorrhage and gangrene of the limb are the great sources of danger here. When gangrene is imminent, or has come on, amputation is necessarily the sole resource. With regard to secondary hæmorrhage supervening after ligature of the artery *at the seat of injury*, there is, I think, no safe course but removal of the limb. Where the artery has been tied higher up, as, for instance, when the external iliac has been ligatured for recent wounds or traumatic aneurisms in the groin or upper part of the thigh, the hæmorrhage appears to have returned, or gangrene to have supervened in all cases. This fact was remarkably illustrated in the Crimean War. Thus Macleod states that the French in one hospital at Constantinople ligatured the femoral at a distance from the wound for secondary hæmorrhage seven times, and that all the cases failed.

If the traumatic aneurism have assumed a *circumscribed* character, it must be treated on the principles laid down for this form of the disease, the supplying artery being ligatured above the tumour: and cases are not wanting in proof of the success of this practice.

It occasionally, though rarely, happens that a **Varicose Aneurism** is formed in the groin or upper part of the thigh, as the result of wound of the artery and vein in this situation. It usually presents the ordinary characters of this disease, but some peculiarities have occasionally been met with. Thus, in a case related by Horner, there was a wavy motion in the femoral vein on the uninjured side, arising from the blood in the wounded vessel communicating a thrill upwards to that contained in the vena cava. In a case related by Morrison, it is stated that a tumour, as large as the human uterus at the third month of pregnancy, communicated with the injured vein.

The *Treatment* of this disease is exceedingly unsatisfactory. Of four cases in which the external iliac artery was tied, a fatal termination occurred in every instance; two of the patients dying of gangrene of the limb, and the remaining two of secondary hæmorrhage and consecutive pneumonia. It was consequently proposed by Guthrie that the tumour be laid open, and the artery secured above and below the aperture in it. As this plan has never been fairly put into practice, it would perhaps be useless to speculate on the chances of success likely to attend it. The danger of a fatal gush of blood on laying open the sac, which in former times would have made most Surgeons hesitate to venture on such an operation, has now been completely obviated by the use of the aorta-compressor.

VESSELS OF THE LEG AND FOOT.—Deep stabs, cuts, and gunshot wounds of the leg may be followed by profuse hæmorrhage from a wounded artery. It may not always be easy to determine with accuracy which of the arteries is wounded: whether it be one of the tibials, the peroneal, or only large muscular branches. This is more especially the case when, in consequence of fracture, a pulsating extravasation of blood forms in the calf. When there is an open wound, the direction taken by it will probably enable the Surgeon to solve the question.

In the *Treatment* of arterial bleeding from the leg, the Surgeon may, especially if it be not very profuse, try to arrest it by compress, bandage, and position. Should these measures fail, recourse must be had to operation.

When the **Posterior Tibial Artery** is wounded, there is no reason to

deviate from the usual principle of treating primary hæmorrhage from a wounded artery, viz., to cut down on the vessel at the seat of injury, and tie it above and below the wound in it. The same rule of treatment applies to **Wounds of the Anterior Tibial and Peroneal Arteries.** In performing this operation, if the posterior tibial be wounded in the upper two-thirds of its course, the Surgeon will have to cut freely by the side of or through the muscles of the calf. This he must do in the direction of their fibres, injuring them by transverse incision as little as possible: and by taking the track of the wound as his guide, the bleeding vessel will at last be reached, and must then be tied in the usual way. Such an operation, practised on a person with a muscular limb that is infiltrated with blood and inflammatory effusions, is in the highest degree difficult. In the lower third of the leg the arteries are superficial, and are reached with comparative ease.

When the hæmorrhage is *secondary*, or if a diffused aneurism have formed, with or without external wound, as in a case of fracture, the Surgeon may, by means of the bloodless method, succeed in applying a ligature to the wounded vessel. Thus, Ruttle, in a case of diffused traumatic aneurism of the calf, which was mistaken for an abscess, successfully ligatured the lower end of the popliteal and both the tibial arteries. Recourse has, however, occasionally been had to ligature of the superficial femoral with success. The vessel may be tied in Scarpa's triangle, or, which would, I think, be better in such a case, in Hunter's canal. If this fails, amputation is necessarily the only resource. In one of the successful cases S. Cooper ligatured the popliteal—a plan that has found favour with the French Surgeons. In another, Dupuytren tied the superficial femoral for a pistol-bullet wound in the leg. The others were cases of diffused aneurism, arising from secondary hæmorrhage occurring in the course of a fracture.

The subject of **Wounds of the Tibial Arteries** as a result of fracture of the tibia, will be more fully discussed in Chapters XX. and XXI.

Small **Circumscribed Aneurisms** are occasionally met with in the foot, in consequence of wound of one of the plantar arteries, as in operations for club-foot. If pressure have failed in preventing or curing the disease, the only course left to the Surgeon is to lay the tumour open, and to ligature the artery on each side in the usual way.

CHAPTER XVII.

ENTRANCE OF AIR INTO VEINS.

THE Entrance of Air into a Wounded Vein, though a rare accident, is one of great interest to the practical Surgeon, as it occurs chiefly in the course of operations.

It was first observed in the year 1818, in a case in which the internal jugular vein was opened during the removal of a large tumour from the right shoulder by Beauchêne, and the subject was afterwards fully investigated by a Commission of the French Academy, by Magendie, Amussat, Cormack, and others.

RESULTS OF EXPERIMENTS ON ANIMALS.—As cases of entry of air into the veins occur comparatively seldom in man, it is necessary to study the phenomena accompanying it on the lower animals. The experiments of Morgagni, Valsalva, Bichat, and Nysten long ago demonstrated the fact that the forcible introduction of air into the circulation would kill an animal. Death in these cases appears to be dependent partly on the quantity of air injected, and partly on the rapidity with which it is thrown in. Bichat supposed that a single bubble would kill with the rapidity of lightning; but this is erroneous. I have on several occasions injected two or three cubic inches of air into the jugular vein of a dog, without producing death, though much distress resulted. The rapidity with which the air is thrown in exercises a considerable influence upon the result: if quickly, a small quantity may kill; if slowly and gradually, a large quantity may be injected without destroying life, the blood apparently absorbing the gas. In experiments I have observed the following phenomena in cases where death was produced.

On exposing the internal jugular vein low in the neck, and puncturing it at a place where the flux and reflux of the blood are plainly discernible, there is perceived in the first inspiratory effort made by the animal after the wound, a peculiar lapping or gurgling, hissing sound; the nature of the sound depending partly on the size and situation of the opening in the vessel. At the same time, a few bubbles of air are seen to be mixed with blood at the orifice in the vein. The entrance of the air is immediately followed by a struggle, during the deep inspirations of which, fresh quantities of air gain admittance, the entrance of each portion being attended by the peculiar sound above described. On listening now to the action of the heart, a loud churning noise will be heard with the ventricular systole; and the hand applied to the chest will feel at the same time a peculiar bubbling, thrilling, or rasping motion, occasioned by the air and blood being whipped together amongst columnæ carneæ and chordæ tendineæ. As the introduction of air continues, the circulation becomes gradually more languid; the heart's action, though being fully as forcible as natural, if not more so. The animal soon becomes unable to stand; if placed upon its feet, it rolls over on one side,

a few plaintive cries, is convulsed, passes faeces and urine, and dies. The thorax be immediately opened, it will be seen that the heart's action is going regularly and forcibly, and that the right cavities, though filled, appear abnormally distended.

It occurs, as I have shown in a paper on this subject, published in the number of the *Edinburgh Medical and Surgical Journal*, in consequence of air and blood being beaten up together in the right cavities of the heart into a spongy froth, which cannot be propelled through the pulmonary artery; hence there is a deficient supply of blood to the brain and nervous system, and fatal syncope comes on, attended usually with convulsions. In addition to this, the frothy mixture in the ventricles has not sufficient resistance to overcome the tendency of the valves of the heart to close upon them, and close the valves of the heart, and the circulation consequently comes to a stand-still.

ACCIDENTAL ENTRY OF AIR INTO THE VEINS OF MAN is attended with peculiar constitutional phenomena.

Local Phenomena.—These consist of a peculiar sound, produced by the escape of the air, and of the appearance of bubbles about the wound in the neck. The sound is of a hissing, sucking, gurgling, or lapping character, and fails to indicate the serious nature of the accident that has occurred. Once heard, whether in man or in the lower animals, it can never be forgotten. It has fortunately fallen to my lot to hear this sound in the human subject on one occasion only, in a patient who had attempted suicide by cutting his throat. The wounded internal jugular was being raised for the purpose of having a ligature passed under it, when a loud hissing and gurgling was heard, and some bubbles of air appeared about the wound; the patient became faint, and greatly oppressed in his breathing. The ligature was immediately tightened, the faintness gradually passed off, and no bad consequences ensued.

Constitutional Effects are usually very marked. At the moment of the entry of the air, the patient is seized with extreme faintness, and a sudden shock about the chest; if he is not unconscious from an anæsthetic he cries out or exclaims that he is dying, and continues moaning. There is a purely cardiac in character, for the air enters the lungs freely; this is dyspnoea is due to the arrest of the supply of blood to the lungs. The becomes nearly imperceptible, though the heart's action is laboured and rapid; the pupils are widely dilated. Death commonly results; but not invariably, in many cases at least. Greene has collected 68 fatal cases of this accident; 24 died almost immediately, the rest at periods varying from a few hours to seven days. Beauchesne's case lived a quarter of an hour after the occurrence of the accident. If the patient survive the immediate effects of the accident, he may recover without any bad symptoms, as happened in the case to which I have referred above, and in an instance recorded by Cooper. In some of the cases that survived some days the fatal result is usually have been due to bronchitis or pneumonia.

CAUSE.—The cause of the entry of air into the veins was very completely investigated by the French Commission. If we open a large vein at the side of a dog's neck, in which the venous pulse, or flux and reflux of the blood is perceptible, we shall see that air rushes in during inspiration only, owing to the tendency to the formation of a vacuum within the thorax during inspiration. This suction action, or "venous inspiration," is confined

to the large vessels in and near the thoracic cavity, being limited by the collapse of the coats of the veins at a little distance from this. If the veins were rigid tubes, it would extend throughout the body; but as they are not, it ceases where the coats collapse. The root of the neck and the axilla where the venous flux and reflux are perceptible have, therefore, been termed the "dangerous region." In certain circumstances, however, air may spontaneously gain admission at points beyond this.

It is well known that what is called by the French Surgeons the "canalization" of a vein, or its conversion into a rigid uncollapsing tube, is the condition which is most favourable to the entry of air. Indeed, except in the so-called "dangerous region," this accident cannot occur unless these vessels be canalized, or, in other words, prevented from collapsing. Canalization may be brought about in a variety of ways. Either the cut vein may be surrounded by indurated tissue, which keeps it open like a hepatic vein; or its coats may have been thickened by inflammation to such a degree as to prevent them falling together when divided. Then, again, some of the veins at the root of the neck, especially the external jugular, have such intimate connections with the cervical fascia that their sides may be held apart when they are cut across. The contractions of the platysma and other muscles of the neck may likewise have a similar effect. In removing a tumour, also, from the lower part of the neck or axilla, the traction exercised upon its pedicle may cause a vein to become temporarily canalized; especially if the section be incomplete and in a transverse direction, when the wound will be rendered open and gaping by the traction upon it. This patency of the incision in the vein is apt to be increased by the position that is necessarily given to the head and arm, in all operations of any magnitude about the axilla and neck. Lastly, the introduction of air into a vein will be favoured by the vessel being divided in the angle of a wound, the vein being made open-mouthed and gaping when the flaps that form the angle are lifted up.

In all cases in which air has entered the veins during operations these vessels were in one or other of the above-mentioned conditions. Thus, in Beauchesne's case, air was introduced in consequence of incomplete division of the external jugular, immediately above the right subclavian, whilst in a state of tension, during the removal of a portion of the clavicle. In a case that occurred to Dupuytren, a large vein connected with a tumour and communicating with the jugular was cut whilst the tumour was being forcibly drawn up. The vein was found to be adherent to the sides of a groove in the growth, so that it remained gaping when cut. In a case related by Delpech, there was thickening of the coats of the axillary vein, causing it to gape like an artery. Ulrick saw the accident occur in consequence of the incomplete division of the internal jugular vein, which was implicated in a tumour in the neck. A similar case happened to Mirault of Angers, the internal jugular being divided to half its circumference. A case occurred to Warren, in which the air entered by the subscapular vein, the coats of which were healthy, but in a state of tension in consequence of the position of the arm; and another, in which the same accident happened from the division of a small transverse branch of communication between the external and internal jugular, whilst in a state of tension. Mott, whilst removing a tumour of the parotid gland, opened the facial vein, which was in a state of tension in consequence of the position of the patient's head, when air was introduced. Begin also relates a

case in which air entered in consequence of the puncture of the internal jugular vein whilst he was removing a tumour from the neck.

These cases show clearly what the Surgeon should particularly guard against in the removal of tumours about the neck and axilla; viz., incomplete division of the veins, and the employment of forcible traction on the diseased mass at the moment of using the scalpel. In removing tumours from the neck and axilla, it is in many cases impossible to avoid drawing them forcibly upwards or forwards, in order to get at their deeper attachments; but if this be necessary the chest should, for reasons that will immediately be pointed out, be tightly compressed, so that no deep inspirations may be made at the moment that the knife is being used, or before a divided or wounded vein can be effectually secured.

Preventive Treatment.—In the pre-anæsthetic days, this accident was of more common occurrence than it is now. When a patient was under the knife, the respirations were generally shallow and restrained, the breath being held, whilst every now and then there was a deep gasping inspiration; at which moment, if a vein were opened in which the pulse were perceptible, or which was canalized, air was necessarily sucked in, in quantity and force proportioned to the depth of the inspiration. In these circumstances, it was recommended that the chest and abdomen should be so tightly bandaged with broad flannel rollers as to prevent the deep gasping inspirations, and to keep the breathing as shallow as possible, consistently with the comfort of the patient. I have often found that the entrance of air into the veins of a dog could be arrested by compressing the chest of the animal, so as to limit the respiratory movements; but that, as soon as a deep inspiratory effort was made, on the compression being removed, a rush of air took place into the vessel. When such precautions were taken, therefore, during an operation about the root of the neck, the Surgeon had to be careful not to remove the compression until the operation was completed, and the wound dressed; for if this precaution was not attended to, the patient would, most probably, on the bandage being loosened, have made a deep inspiration, and air might have been sucked in at the very moment when all appeared safe. It is now rarely possible to adopt these precautionary measures, for the danger from applying such constriction during the administration of an anæsthetic would be greater than the risk of entrance of air, but I have allowed this description of them to remain partly on historic grounds and partly because circumstances might even now arise in which they might be necessary.

In the removal of cancerous glands or other tumours from the axilla, it is sometimes possible to compress the vein, between the heart and the place of operation.

Curative Treatment.—Different plans have been recommended for the treatment of those cases in which air has gained admittance into a vein; but, from the very fatal nature of this accident, it does not appear that much benefit has resulted from any of them: the recovery of the patient, in some of the cases, appearing to be due rather to the quantity of air that was introduced being insufficient to cause death, than to any effort on the part of the Surgeon. The suggestion of Amussat and Blandin, to empty the heart of the mixture of blood and air by suction through a tube passed into the wound in the vein, or into an opening made into the right jugular, can hardly be considered within the range of practical Surgery. The compression of the

chest recommended by these observers, and by Gerdy, however valuable it may be in preventing the ingress of air, can, when it has once been introduced into the veins, have no effect in removing it. Bleeding from the temporal artery, opening the right jugular vein, and even tracheotomy, are other measures which have been recommended, but are unlikely to be productive of anything but harm.

1. What, then, are the measures that a Surgeon should adopt? Beyond a doubt, the first thing to be done is to **prevent the further ingress of air**, by compressing the wounded vein with the finger, and, if practicable, securing it by a ligature, as it is only when the air that is introduced exceeds a certain quantity that death ensues. All further entry of air having been thus prevented, our next object should be to **keep up a good supply of blood to the brain and nervous centres**, and thus maintain their activity. The most efficient means of accomplishing this would probably be the plan suggested by Merrier, who recommends us to compress the abdominal aorta and axillary arteries, so as to divert the blood that may pass through the lungs to the encephalon. This appears to me to be the most effectual way of carrying out the indication. The patient should, at the same time, be placed in a recumbent position, so as to facilitate the afflux of blood to the head. The compression of the axillary and femoral arteries may readily be made by the fingers of two assistants.

2. **To maintain the action of the heart** until the obstruction in the capillaries of the lungs can be overcome or removed, artificial respiration should be resorted to as the most effectual means of keeping up the action of that organ. It also helps the circulation through the lungs, and thus relieves the right side of the heart. Sylvester's method of artificial respiration is the best, see (Chap. XXVII.) but before employing it, it will be necessary to remove everything that compresses the chest, or interferes in any way with the free exercise of the respiratory movements. Friction with the hand over the precordial region, and the stimulus of ammonia to the nostrils, may at the same time be resorted to.

3. The third indication—that of **overcoming the obstruction in the pulmonic capillaries**—would probably be best fulfilled by the means adopted to maintain the heart's action, viz., artificial respiration. That the action of respiration, if kept up sufficiently long, will enable the capillaries of the lungs to get rid of the air contained in them, appears to be certain: for I have experimentally observed that, if a certain quantity of air be introduced into the jugular vein of a dog, and artificial respiration be then established, and maintained for half or three-quarters of an hour, a very small quantity indeed, if any, will be found, on killing the animal, in the cavities of the heart, or in the branches of the pulmonary vessels. I am aware that this is not altogether conclusive, as the air might be dissolved in the blood, or might still exist in the capillaries of the lungs, although none might be found in the larger branches of the pulmonary artery; but still it seems to me that we can hardly account for the large quantity of air that will disappear when artificial respiration is kept up, in any other way than by assuming that some, if not all of it, passes out of the capillary vessels into the air-cells of the lungs.

CHAPTER XVIII.

SPECIAL INJURIES OF NERVES, MUSCLES, AND TENDONS.

INJURIES OF NERVES.

CONTUSION.—Nerves are often contused; the injury producing a tingling sensation at their extremities, and pain at the part struck. These effects usually pass off in the course of a few minutes or hours. If the blow have been sufficiently severe to cause hæmorrhage amongst the fibres of the nerve, the symptoms may be more severe and persistent, and temporary paralysis of the parts supplied by the injured nerve may result. Most commonly sensation is merely impaired, even when the motor paralysis is complete. In hysterical women, the symptoms may last for a considerable period, and even slight contusions may give rise to very persistent neuralgia. In other cases the continuance of the symptoms appears to be due to the supervention of chronic neuritis (see p. 497).

STRAINS.—Any movement, which stretches a nerve forcibly, may be slowly followed by the symptoms of chronic neuritis to be described later on (p. 497). This is most common in the nerves of the brachial plexus.

COMPRESSION.—This most commonly arises from the pressure of tumours or aneurisms, but it may be the result of injury; thus, the brachial plexus may be pressed on by the head of the humerus in a dislocation, the spinal nerves may be compressed at the intervertebral foramina in cases of fracture of the spine, and the fragments of bone in a fracture of a limb may press on contiguous nerves. Another common form is the so called crutch-palsy, resulting from the pressure of the upper end of the crutch upon the nerves of the brachial plexus; a similar paralysis of the muscles of the front of the leg is not uncommonly met with, as the result of pressure on the external popliteal as it winds round the head of the fibula, from splints applied without sufficient padding; and I have known of three cases in which the musculospiral nerve was paralysed from the arm hanging over the edge of the table during a prolonged operation. In these cases sensation is little, if at all, impaired. Nerves may also be compressed by the growth of callus from a fractured bone, or by the contraction of a scar. The effects of pressure are proportional to its severity and duration. The mildest effects are the numbness, tingling, and sense of weakness with which everyone is familiar as a consequence of pressure on the ulnar nerve from sleeping with the arm under the head. If it lasts for a sufficient length of time, and is sufficiently severe, complete loss of sensation and paralysis are produced in the parts supplied by the nerve pressed upon, followed by wasting and degeneration of the muscles. Such cases usually recover in time, if the cause be removed and the limb be afterwards treated by the methods described later on.

RUPTURE OR LACERATION.—Healthy nerves are rarely torn across except in the most severe injuries, such as compound dislocations and compound fractures. When paralysis or loss of sensation follows a subcutaneous injury, it is due to contusion, and possibly to rupture of some of the fibres, but the continuity of the nerve is scarcely ever completely interrupted.

PUNCTURE.—If a nerve be punctured, the parts below the puncture become the seat of tingling, shooting, and burning pains, and the neuralgic condition may travel upwards along the nervous trunk. Thus, I have more than once seen a puncture of one of the digital branches of the ulnar nerve produce a kind of painful paralysis of its trunk, rendering the arm nearly useless. I have seen the same effects occur in the median nerve from a needle puncture of the finger. It occasionally happens, in venesection at the bend of the arm, that a branch of the internal cutaneous nerve is pricked, and that very persistent neuralgia occurs in consequence.

DIVISION.—Primary Effects.—When a nerve is completely cut across, or its conducting power is in any way abolished, whether by contusion, compression, or laceration, paralysis of sensation or motion, or both, according as the nerve is sensory, motor, or mixed, occurs in all the parts supplied by it. The vaso-motor paralysis that arises from the division of the nerve at first causes hyperæmia, with some elevation of temperature, which only lasts for a few days and then gradually subsides till in a week or two the part becomes passively congested and colder than natural. The patient complains of numbness or deadness in the parts supplied by it, and sensibility of every kind is lost; but various anomalous painful sensations of a burning, tickling, tingling, or creeping kind are complained of. These sensations often give the idea of increased heat of the part to the patient, and are compared by him to the effect that would be produced by molten lead or boiling water running through it. When the nerve is partially divided, or bruised as well as severed, as in cases of gunshot injury, neuralgia in the parts supplied by it beyond, and sometimes also in those above, the seat of injury, is associated with the paralytic symptoms.

The **Secondary Effects** of division differ according to the nature of the nerve.

The section of a purely *motor nerve*, such as the facial, causes complete paralysis, with subsequent wasting and degeneration of the muscles supplied by it, but the nutrition of the superficial structures is not affected.

The changes in the muscles in these cases are of great importance. From the moment the nerve is divided, all voluntary power is of course lost. The conductivity of the nerve is rapidly abolished; it begins to be lowered at the middle of the first week, and at the end of the second week stimulation of the lower end of the divided nerve with the constant or interrupted current fails to cause any muscular contraction.

Direct excitation of the muscle shews that during the first two weeks after the nerve section the irritability to the voltaic and faradic currents are both lowered. The faradic excitability now entirely disappears, whilst at the same time the contractions produced by the constant current become excessive and remain so for several months, after which the excitability falls and disappears altogether in a year or more. These reactions are most useful guides in diagnosis, prognosis, and treatment. As the muscles become flabby and wasted, deformities of various kinds may ensue, from the unopposed action of

the unaffected muscles of the limb, or from shortening of the paralyzed and atrophied muscles, should their points of attachment be approximated by the position in which the limb is placed.

The division of a purely *sensory nerve*, such as a branch of the fifth, completely abolishes sensation in the part supplied by it, but does not necessarily cause any serious disturbance of nutrition. This is probably due to the free communication between the various nerves of the face. Arloing and Tripier have shown by experiment that, after the division of a superficial sensory nerve, the neighbouring cutaneous nerves which communicate with the terminal branches of the one divided rapidly assume its functions so that sensibility may return in a few days without repair of the divided nerve. If the whole trunk of the fifth nerve is destroyed together with the Casserian ganglion, serious interference with nutrition follows, such as ulceration of the cornea or of the nasal mucous membrane. In central disease affecting the fifth nerve, the ganglion remaining intact, trophic changes do not occur, although, from loss of sensibility, the parts supplied by it are prone to suffer from injury. It may, in fact, be stated as a general rule that grave trophic changes do not occur unless a part is completely cut off from all communication with a healthy nerve-centre.

After the division of a *mixed nerve*, such as the ulnar, the nutrition of the part supplied by it is seriously modified. The muscles, as before stated, degenerate and waste. The whole part supplied by the injured nerve becomes congested, bluish, and, after a temporary rise of temperature in some cases, colder than natural. The fall of temperature is often very marked. Thus, I found in a woman who was under my care for a wound of the forearm, in which the ulnar nerve had been divided, that, twenty-one days after the injury, the temperature between the ring and the little finger of the injured side was 9° Fahr. below that of the same spot on the opposite hand. Sometimes the part becomes oedematous; the skin often becomes rough and peels, but more commonly it is smooth, red and shining—the “glossy skin” of Paget; the nails grow badly, and are brittle or scaly, and abnormally curved longitudinally. Gradually increasing stiffness, with sometimes painful swelling, of one or more of the joints of the fingers may occur. Blebs, the contents of which become purulent, not uncommonly form on the tips of the fingers. Chilblains are readily produced by slight exposure to cold, and they frequently become vesicular or slough, leaving sluggish and unhealthy ulcers. Wounds in such parts heal badly, and are peculiarly prone to be affected by unhealthy spreading inflammations. If the patient be a growing child, the development of the affected part will be more or less completely arrested.

If union takes place between the opposite ends of the divided nerve, the various phenomena that have just been described gradually disappear, and complete restoration, first of sensation and afterwards of motion, with a return to the normal nutrition of the part, eventually takes place. Some voluntary motion usually returns in the muscles before electrical irritability is re-established. In many cases, however, especially if a piece of the nerve have been removed, or if the wound in which it has been divided heal by the second intention, recovery fails to take place. Under these circumstances, the central end becomes bulbous, just as in similar conditions in stumps, and it may then become the seat of intense neuralgic pains darting downwards to

the terminal branches and upwards along the trunk of the affected nerve.

Pathology.—If a nerve be completely divided its two ends retract very slightly: not more than a sixteenth of an inch. In cases which have been examined at a later period, the separation has been found to have increased to about a third or half an inch, or even more. *Degeneration* sets in in the peripheral end about four days after it has been cut off from its communication with the nerve-centres. The nuclei of the primitive sheath of Schwann proliferate. The medullary sheath undergoes segmentation, then breaks up into irregular globules and finally disappears entirely in about a month. The axis-cylinder degenerates at a later period, but after some weeks it also breaks up and disappears. The nerve then consists merely of the shrunken sheath of Schwann, containing some granular protoplasm and nuclei, and the connective tissue of the fibrous sheath. In the central end degeneration extends only a very short distance from the injury, and commences at a later period. Within a few weeks of the injury the proximal end will always be found to have become more or less distinctly bulbous, the bulb being composed of fibrous tissue in which many new nerve fibres are commonly found. Bowley states that the *regeneration* of the distal end may occur without union of the divided nerve, but Ranvier believes this takes place only when there are free communications between the fibres of neighbouring nerves and those of the divided nerve. In a case lately in University College Hospital the state of the nerves confirmed this latter view: three years after division the distal end of the ulnar, which has but few communications with any other nerve, showed no signs of regeneration, while that of the median which communicates freely with the radial, which was not divided, contained multitudes of tubules with healthy medullary sheaths. When the ends of the divided nerve are brought in contact directly after division it has been asserted that *immediate union* may occur. It is difficult in any other way to explain the fact that in some exceptional cases sensation has commenced to return in the parts supplied by the divided nerve within twenty-four hours of the approximation of the ends by suture. Under ordinary circumstances the first step is the formation of a bond of union between the two ends composed of a delicate spindle-cell tissue. By what process the new nerve-tubules are developed in this mass of young connective tissue is still doubtful. Cornil and Ranvier assert that a growth takes place from the axis-cylinders of the proximal end which penetrate the new tissue and communicate with the lower end, becoming subsequently clothed with the medullary sheath. Before the nerve can resume its functions, the whole peripheral part, which has, as before stated, undergone degeneration, must be regenerated. The regeneration of the degenerated tubules is believed to take place from the nuclei of the sheath of Schwann, which remain even in the atrophied nerve after the medullary sheath and axis-cylinder are gone. These multiply and join with each other to form the new axis-cylinder, which subsequently becomes surrounded by the medullary sheath. The process of regeneration is said to proceed gradually down the nerve from the injured spot. The restoration of a divided nerve is in most cases slow, and is often not complete for from three months to a year. The period at which signs of returning function have manifested themselves varies much. In some rare cases sensation has commenced to return in from twenty-four hours to six days, in others not for many months.

TREATMENT OF INJURIES CAUSING INTERRUPTION OF THE CONDUCTING POWER OF A NERVE.—The treatment of these injuries may be divided into two parts: 1st, the *Local treatment of the Injured nerve*, and 2ndly, the *Treatment of the Paralyzed part*.

1. The **Local Treatment**.—In cases of *subcutaneous injury* nothing should be done, for it may be taken for granted that, although the nerve may be completely paralysed, its continuity is not destroyed. On dissecting limbs amputated for the most severe railway or machinery accidents, the nerves are almost invariably found untorn in the midst of the crushed tissues. To cut down, therefore, in a subcutaneous injury with the intention of suturing the nerve would be a grievous error. When the function of the nerve is abolished by *pressure*, the cause of pressure must be removed if possible, as by the cure of an aneurism, the excision of a tumour, or the reduction of a dislocation. When the cause of the paralysis is the *implication of the nerve in a cicatrix or in the callus of a fracture*, nothing should be done locally until, after waiting many months, it becomes evident that nature will not effect a cure. It will very rarely be found necessary in such cases to adopt any operative plan of treatment, the symptoms disappearing as the scar becomes looser with age, or as the provisional callus of the fracture is absorbed. Warren, however, relieved a case of neuralgia resulting from implication of a nerve in cicatricial tissue by dissecting it out without dividing or otherwise injuring it.

Primary Suture.—In cases of *division of a nerve in an open wound* no doubt exists as to the proper line of treatment: the two ends of the nerve should be found and carefully secured to each other by fine sutures. The best material for suture is very fine chromic catgut. Silk, which would not be absorbed for many weeks, might cause irritation and possibly severe neuralgia. The needle should be a common round sewing needle, which, if necessary, can be bent into a curve in the flame of a spirit-lamp and hardened again by being dipped in cold water; the ordinary flat surgical needle, with its cutting edges, needlessly damages the nerve. The end of the nerve should not be pinched with the forceps, as this may prevent rapid union. The sutures should be passed completely through the nerve, not through the sheath only, as this ensures better approximation of the ends. Three or four sutures having being applied, according to the size of the nerve, the wound must be closed and treated by some antiseptic method if possible; suppuration being usually fatal to success. The limb must be put in such a position as completely to relax the nerve. In a large proportion of the cases union will be obtained, with restoration of function.

The *prognosis* after primary nerve suture is good, but the period at which restoration of function may be expected varies greatly. Reference has already been made to these exceptional cases in which a rapid return of function has suggested the occurrence of primary union. Bowlby concludes from the consideration of a large number of cases that recovery may occur after weeks, months, or years; he finds that improvement usually begins within a year, but that a case cannot be looked upon as quite hopeless until the lapse of two or three years.

Secondary suture may be undertaken if the primary operation has failed, or if an attempt was made to suture the nerve at the time of the injury.

The operation is performed by freely exposing the nerve after rendering the limb bloodless. Its proximal extremity can sometimes be found by its bulbous

condition, which may perhaps be felt; the lower end is often atrophied and more difficult to find. The ends of the nerve may then be pared, so as to remove the dense scar-tissue with which they are covered, but no more should be taken away than is absolutely necessary. After this they are sutured as in a fresh wound. Great care must be taken to relax the nerve by a suitable position of the limb. The operation of nerve-grafting has met with sufficient success to justify its trial in cases where it is found impossible to approximate the ends of the nerve.

Prognosis.—Bowlby has collected 73 cases of secondary nerve suture, in 32 of which the result was successful, in 26 partially successful, whilst in 15 no improvement followed. The ultimate results were, however, probably more favourable than these figures indicate, as many of the cases, especially the partially successful ones, may have continued to improve later. Great improvement may be confidently expected, and no case must be despaired of until several years have passed. The operation should be undertaken, however long the time may be that has elapsed since the injury, and however marked may be the atrophy of the paralysed muscles.

2. Treatment of the Paralyzed Limb.—In all those cases in which the nerve is not completely divided, treatment of the paralyzed parts is alone possible, the object being to prevent wasting and to maintain the nutrition of the limb in such a way that, when restoration of the nerve takes place, the muscles shall be in a state to respond to the influence of the will. Much can be done by judicious treatment to maintain the temperature, to avoid the formation of chilblains and other sores, to prevent the development of deformities, and in children or young subjects to keep up the growth. In order to keep up the nutrition and to overcome the congestion which is always met with in the paralyzed part, it must be made of a healthy red colour at least twice a day. There is no more efficient means of doing this than the use of the continuous electric current. The sponge connected with the positive pole of the battery may be applied over the course of the nerves, while the limb is freely sponged with the other. At the same time each separate muscle should, if possible, be made to contract by slow interruptions of the current. In a minute or more the whole paralyzed part will become bright red. In the absence of the battery, much may be done by properly applied rubbing. The part should be carefully protected by warm clothing, and the patient should be encouraged to use it as much as possible. If only a single group of muscles is paralyzed, properly designed apparatus may be required to overcome the deformity which ensues, but this should never be used if it can be avoided, as it interferes to some extent with the use of the limb.

TRAUMATIC NEURITIS.—This disease may follow almost any injury of a nerve. It is most common in civil practice as the result of bruises or strains, and is sometimes connected with gout or rheumatism. In wounds it seldom arises unless union has taken place by the second intention with inflammation and suppuration; and, consequently, it is a rare affection in amputation stumps. In gunshot wounds, in which the nerves are often contused and partially divided and in which the wound almost always heals with suppuration, it is more common.

Pathology.—Acute inflammation may affect a nerve-trunk in the neighbourhood of a suppurating wound; the nerve is swollen and congested, there is infiltration of its connective tissue with inflammatory products, and the

fibres themselves may exhibit degenerative changes. In chronic inflammation we find an overgrowth of the connective tissue of the epineurium and perineurium; whilst in the later stages the areolar tissue in the fasciculi becomes affected, and degeneration of the nerve fibres occurs. These changes are well seen in Fig. 155, from a case in which Sands and Seguin, of New York, excised the cords of the brachial plexus. The changes of chronic traumatic neuritis tend slowly to ascend the nerve, and may even extend to the cord and give rise to sclerosis.

Symptoms.—The symptoms of traumatic neuritis are intense pain and tenderness in the line of the affected nerve. Sensation is variously modified in the parts supplied by the nerve; there may be numbness, or tingling, or *anesthesia*; in other cases there may be intense neuralgic pain. Occasionally there are spasms, but more commonly there is weakness or paralysis of some of the muscles supplied. Poore has shown that in a considerable proportion of the cases which have come under his care for loss of writing-power, tenderness has been found in the course of some one or more of the nerves of the arm, and on tracing the history, the origin of the affection was frequently found to be a strain or other injury. In one case recorded by him, the whole brachial plexus in the axilla became intensely tender after a violent strain of the shoulder. The patient's sufferings were very great, and nothing gave him much relief. At last, after prolonged rest, the symptoms subsided, and it was then found that the serratus magnus was paralysed. Finally, this also recovered. In hysterical patients the symptoms are often greatly exaggerated.

Treatment.—In the early and painful stage of the disease, electricity aggravates the mischief. The tender nerves should be freely blistered, and the affected limb kept at perfect rest. When the symptoms are less intense a long strip of capsicum plaster applied along the line of the nerve gives much relief. If any constitutional condition such as gout, rheumatism, or syphilis can be detected, it must be treated by appropriate means. These cases are always chronic, often lasting many months before the symptoms disappear. In others, all milder means having failed, surgical operations of various kinds have been undertaken for the relief of the patient. These operations are of three kinds:—1. Excision of the bulbous ends of the nerves in cases of neuritis following amputation; 2. Division or excision of a portion of the affected nerve; and 3. Nerve-stretching.

1. **Excision of the Bulbous Ends of the Nerves.**—This has been undertaken usually under the impression that the bulbous end was the seat of the mischief. In some cases no doubt a painful stump is due to implication of the end of the nerve in the cicatrix, and then relief is given by the operation. If however the symptoms are due to true chronic ascending neuritis, this operation, although occasionally giving relief for a short time, is never productive of a cure.

2. **Division or excision of portions of the Nerve.**—The smaller nerves of the limbs have repeatedly been divided or partially excised, in cases of persistent traumatic neuralgia. The larger nervous trunks, such as the median, musculo-spiral, and ulnar, have been treated in the same way in the upper limb; and the external popliteal, and even the sciatic nerve in the lower limb, has been partially excised as a last resource in extreme cases. These operations have in some cases effected a permanent cure, in others they have been followed by only temporary relief.

condition, which may perhaps be felt; the lower end is often atrophied and more difficult to find. The ends of the nerve may then be pared, so as to remove the dense scar-tissue with which they are covered, but no more should be taken away than is absolutely necessary. After this they are sutured as in a fresh wound. Great care must be taken to relax the nerve by a suitable position of the limb. The operation of nerve-grafting has met with sufficient success to justify its trial in cases where it is found impossible to approximate the ends of the nerve.

Prognosis.—Bowlby has collected 73 cases of secondary nerve suture, in 32 of which the result was successful, in 26 partially successful, whilst in 15 no improvement followed. The ultimate results were, however, probably more favourable than these figures indicate, as many of the cases, especially the partially successful ones, may have continued to improve later. Great improvement may be confidently expected, and no case must be despaired of until several years have passed. The operation should be undertaken, however long the time may be that has elapsed since the injury, and however marked may be the atrophy of the paralyzed muscles.

2. Treatment of the Paralyzed Limb.—In all those cases in which the nerve is not completely divided, treatment of the paralyzed parts is alone possible, the object being to prevent wasting and to maintain the nutrition of the limb in such a way that, when restoration of the nerve takes place, the muscles shall be in a state to respond to the influence of the will. Much can be done by judicious treatment to maintain the temperature, to avoid the formation of chilblains and other sores, to prevent the development of deformities, and in children or young subjects to keep up the growth. In order to keep up the nutrition and to overcome the congestion which is always met with in the paralyzed part, it must be made of a healthy red colour at least twice a day. There is no more efficient means of doing this than the use of the continuous electric current. The sponge connected with the positive pole of the battery may be applied over the course of the nerves, while the limb is freely sponged with the other. At the same time each separate muscle should, if possible, be made to contract by slow interruptions of the current. In a minute or more the whole paralyzed part will become bright red. In the absence of the battery, much may be done by properly applied rubbing. The part should be carefully protected by warm clothing, and the patient should be encouraged to use it as much as possible. If only a single group of muscles is paralyzed, properly designed apparatus may be required to overcome the deformity which ensues, but this should never be used if it can be avoided, as it interferes to some extent with the use of the limb.

TRAUMATIC NEURITIS.—This disease may follow almost any injury of a nerve. It is most common in civil practice as the result of bruises or strains, and is sometimes connected with gout or rheumatism. In wounds it seldom arises unless union has taken place by the second intention with inflammation and suppuration; and, consequently, it is a rare affection in amputation stumps. In gunshot wounds, in which the nerves are often contused and partially divided and in which the wound almost always heals with suppuration, it is more common.

Pathology.—Acute inflammation may affect a nerve-trunk in the neighbourhood of a suppurating wound; the nerve is swollen and congested, there is infiltration of its connective tissue with inflammatory products, and the

fibres themselves may exhibit degenerative changes. In chronic inflammation we find an overgrowth of the connective tissue of the epineurium and perineurium; whilst in the later stages the areolar tissue in the fasciculi becomes affected, and degeneration of the nerve fibres occurs. These changes are well seen in Fig. 155, from a case in which Sands and Séguin, of New York, excised the cords of the brachial plexus. The changes of chronic traumatic neuritis tend slowly to ascend the nerve, and may even extend to the cord and give rise to sclerosis.

Symptoms.—The symptoms of traumatic neuritis are intense pain and tenderness in the line of the affected nerve. Sensation is variously modified in the parts supplied by the nerve; there may be numbness, or tingling, or anesthesia; in other cases there may be intense neuralgic pain. Occasionally there are spasms, but more commonly there is weakness or paralysis of some of the muscles supplied. Poore has shown that in a considerable proportion of the cases which have come under his care for loss of writing-power, tenderness has been found in the course of some one or more of the nerves of the arm, and on tracing the history, the origin of the affection was frequently found to be a strain or other injury. In one case recorded by him, the whole brachial plexus in the axilla became intensely tender after a violent strain of the shoulder. The patient's sufferings were very great, and nothing gave him much relief. At last, after prolonged rest, the symptoms subsided, and it was then found that the serratus magnus was paralysed. Finally, this also recovered. In hysterical patients the symptoms are often greatly exaggerated.

Treatment.—In the early and painful stage of the disease, electricity aggravates the mischief. The tender nerves should be freely blistered, and the affected limb kept at perfect rest. When the symptoms are less intense a long strip of capsicum plaster applied along the line of the nerve gives much relief. If any constitutional condition such as gout, rheumatism, or syphilis can be detected, it must be treated by appropriate means. These cases are always chronic, often lasting many months before the symptoms disappear. In others, all milder means having failed, surgical operations of various kinds have been undertaken for the relief of the patient. These operations are of three kinds:—1. Excision of the bulbous ends of the nerves in cases of neuritis following amputation; 2. Division or excision of a portion of the affected nerve; and 3. Nerve-stretching.

1. Excision of the Bulbous Ends of the Nerves.—This has been undertaken usually under the impression that the bulbous end was the seat of the mischief. In some cases no doubt a painful stump is due to implication of the end of the nerve in the cicatrix, and then relief is given by the operation. If however the symptoms are due to true chronic ascending neuritis, this operation, although occasionally giving relief for a short time, is never productive of a cure.

2. Division or excision of portions of the Nerve.—The smaller nerves of the limbs have repeatedly been divided or partially excised, in cases of persistent traumatic neuralgia. The larger nervous trunks, such as the median, musculo-spiral, and ulnar, have been treated in the same way in the upper limb; and the external popliteal, and even the sciatic nerve in the lower limb, has been partially excised as a last resource in extreme cases. These operations have in some cases effected a permanent cure, in others they have been followed by only temporary relief.

Sands, of New York, removed a section of the whole brachial plexus close to the exit of the nerves from the spinal column. This was done in a lad aged eighteen, whose right arm had been seriously injured in firing a salute. The arm was amputated, but the patient suffered the most agonizing torture from chronic nerve-lesion high up in the limb. So great were his sufferings that he became uncontrollable in his actions, and, although perfectly sane, gave way to fits of the most intense excitement. The operation consisted in making an incision along the outer border of the right sterno-mastoid, and a transverse one following the line of the clavicle. The J-shaped flap was turned up, the carotid sheath and its contents carried to one side, and the brachial plexus

Fig. 155. Section from Lower Cord of Brachial Plexus near Intervertebral Foramina, showing the course of Chronic Neuritis (Sands and Seegar).

- a. Severely fasciculi, showing atrophied fibres (fibres not much larger, under 200 diam., than those of normal nerve under 400 diam.). Very few axon cylinders present. These fasciculi are increased.
- b. Small nerve trunks, separated from others by overgrowth of endoneurium.
- c. Hypertrophied perineurium and epineurium. Sheath of fasciculi no longer distinct.
- d. Dilated blood vessels, surrounded by altered connective tissue.
- e. Yellow granular pigment lying in areolar tissue, mostly in neighbourhood of vessels.

exposed. Pieces fully a quarter of an inch in length were cut out from the four lower cervical and first dorsal nerves, and from one of these Fig. 155 was taken. Considerable relief from suffering followed the operation.

3. **Nerve-stretching.**—This operation was introduced by Nussbaum as a mode of treating intense neuralgia following injury. In a case of this kind affecting the arm, and resulting from gunshot injury, he cut down and stretched the ulnar nerve, then the nerves surrounding the brachial artery, and lastly, the brachial plexus itself. The result was a perfect cure. Since then the operation has been extensively practised.

Under the name of "nerve-stretching" two distinct operations are included. In operating on the larger trunks the nerve is exposed, cleanly isolated for an inch or more, and forcibly stretched either by passing the finger beneath it,

as in the case of the sciatic, or by means of a hook : but on account of the size and strength of the nerve its power of conduction is never completely destroyed, even if considerable force be used, although there may be some modification in its function. In operations on the smaller nerves, as the facial, the nerve is exposed and stretched with a hook, and it will always be found, if moderate force be used, that conducting power is as completely abolished as if the nerve had been divided. This operation is therefore equivalent to division, the only difference being that, as the continuity of the nerve is not destroyed, restoration of function is certain to take place sooner or later.

The most complete account of nerve-stretching in the English language is that given by Marshall in the Bradshaw Lecture delivered at the Royal College of Surgeons in 1883, to which the reader is referred for fuller information on the subject.

Nerves possess but slight extensibility and elasticity, but their cohesion or strength is very great. The breaking-strain of a nerve varies necessarily with its size. Thus that of the supra-orbital is said to be about six pounds, while a healthy sciatic will support 1·8 of the weight of the body, or in a healthy man about 270 lbs. When a nerve is steadily stretched longitudinally with moderate force, the strain is borne at first almost entirely by the fibrous tissue composing the sheath. The nerve-fibres are straightened and the spaces between them narrowed, and thus the vessels and lymph-spaces could be squeezed and emptied of their contents. When the strain is increased to about two-thirds of the breaking-strain and continued for some minutes, it comes to act more directly on the tubules, and produces very definite changes in their structure. The first effect observed is fissuring or cleavage of the medullary sheath. A still more forcible strain causes the medullary sheath to be broken up into irregular masses. If still greater force be applied the axis-cylinder and the tubular sheath may be ruptured. This degree of injury can hardly be inflicted in actual practice when stretching a large nerve by longitudinal traction with the finger and thumb. In stretching a nerve transversely with a hook the medullary sheaths are commonly ruptured and disintegrated at the point of pressure, and the axis-cylinder ruptured, the continuity of the nerve being thus practically interrupted.

The rationale of the effects of nerve-stretching for the relief of chronic neuritis was first suggested by Marshall. The fact that in neuritis the nerve itself is tender, and that, as a rule, the pain is not referred to the parts supplied by the affected nerve, led him to the conclusion that the nerve-trunks must contain sensory fibres distributed in their sheaths, or *nervi nervorum*. At the time this suggestion was made, although sympathetic fibres accompanying the vessels had been demonstrated in nerves by Sappey, no others had been recognised. Victor Horsley, following up Marshall's suggestion, has, however, clearly shown that short medullated fibres terminating in tactile corpuscles exist in the perineurium and epineurium of all nerves. The pain and tenderness in the nerves in neuritis may, therefore, be explained by the pressure upon those *nervi nervorum* by inflammatory exudations and new connective tissue. In stretching a nerve the strain is first borne by the sheath, and it is not until very considerable force is applied that the proper tubules of the nerve begin to suffer. It is easy to understand, therefore, how the *nervi nervorum* ramifying in the sheath may be strained or ruptured to such an extent as to destroy their conducting power, and thus render the nerve itself

without abolishing the power of the nerve to transmit sensory and motor impulses through its proper tubules.

The *secondary effects of nerve-stretching* are the same as those of other causes of laceration. If force sufficient to disintegrate the medullary sheath and so interrupt the conductivity of the nerve is used, the degenerative changes already described as occurring after section of a nerve take place.

The Operation of Nerve-Stretching.—The nerve is exposed by an incision parallel to its course, unless this would needlessly damage neighbouring parts. It must be separated cleanly from the fat and areolar tissue surrounding it for a sufficient distance, and then raised from its bed with a blunt hook or with the fore-finger. If the nerve be of sufficient size it is seized between the finger and thumb and steady traction made upon it, as much as possible in the direction of its course. It should be stretched both centrifugally and centripetally, and the traction should be maintained for about five minutes in each direction. In the case of a small nerve, such as one of the branches of the fifth or the facial, two hooks are passed beneath, which are then separated from each other with sufficient force thoroughly to stretch the trunk without actually tearing it across. The force to be used necessarily varies with the size of the nerve. The sciatic may safely be stretched with a force of thirty pounds, which is about as much as can be exerted when grasping the nerve between the finger and thumb. In a fresh dead body the head may be raised by a hook under the facial nerve without tearing it across, but a smaller degree of force must be used in operating on the living body. The Surgeon must use his judgment in the force he employs in stretching the various nerves. The after-treatment of the wound presents nothing peculiar, but every effort should be made to secure union by the first intention, otherwise the operation may serve as a starting-point for neuritis.

Bloodless nerve-stretching has been suggested in the case of the sciatic. This is done by flexing the thigh upon the abdomen while the knee is bent. The leg is then gradually but forcibly extended. In this position the sciatic nerve is thoroughly put on the stretch.

Physiological Effects of Nerve-Stretching.—It may at once be stated that the effect of stretching a small nerve on a blunt hook, even if only a moderate degree of force be used, is completely to interrupt its physiological continuity, abolishing sensation or voluntary motion or both, according to the nature of the nerve, in the parts supplied by it. In the case of a larger nerve stretched between the finger and thumb, a slight stretching seems to increase its conducting power to sensory and motor impulses of all kinds. A stronger pull impairs the function of the sensory fibres, causing numbness, or even complete anaesthesia, and if still more force be used motor paralysis may be induced. There is no conclusive evidence that nerve-stretching, however forcible, produces any mechanical or functional effect on the nerve-centres.

Results.—Nerve-stretching has been employed in a great variety of disease besides cases of true neuritis, and these will be referred to in subsequent chapters. Marshall gives a table of 512 cases, collected from various sources. In 154 of these the operation was performed for neuralgia of the upper or lower limb, and were probably cases of true nerve-stretching without interruption of the physiological continuity of the nerve. In 108 the operation resulted in a cure, in 26 it gave rise to permanent improvement, in 119 it gave only temporary relief, and in 9 it failed, and one of these terminated in the death

of the patient. Nerve-stretching seems, therefore, in these cases to be very successful, and as it is practically free from danger it should always be adopted when milder means have failed.

INJURIES OF MUSCLES AND TENDONS.

CONTUSIONS.—Muscles are frequently bruised by violent blows or falls, a few fibres being often ruptured. The chief signs of this injury are a sense of inability to use the muscles, and great pain on attempting to do so. There is tenderness on pressure over the bruised spot, but passive movements do not cause pain so long as they do not put the injured fibres on the stretch. By careful attention to these points, it is easy to distinguish these injuries from fractures of neighbouring bones, which they sometimes resemble—especially in the neighbourhood of the shoulder-joint.

SPRAINS OR STRAINS of muscular parts, without rupture of fibres, are of very common occurrence, especially about the shoulder, the hip, and the loins, and are accompanied by much pain and stiffness, and by inability to move the part. When they occur in rheumatic subjects, these injuries not uncommonly give rise to severe and persistent symptoms; painful atrophy, rigidity, or local paralysis of the injured muscle being induced in some cases. It is then often difficult to determine how much is due to the direct strain of the muscle, and how much to chronic neuritis resulting from a simultaneous strain of the nerves. When complete atrophy of a muscle preceded by much pain follows a strain, it is probable that the nerves have been implicated in the injury.

In the **Treatment** of these accidents, when recent, it will be found that kneading or rubbing the part with a stimulating embrocation gives relief, but, if the pain be severe, the application of hot fomentations with rest is more effectual. In the later stages, blisters applied to the points at which the pain is most severely felt are often beneficial. If the injury occur in persons of a rheumatic diathesis, the effects are much more severe and persistent than in those who are otherwise constituted. In such persons, douches, frictions, and passive motion will, after a time, be necessary, together with proper constitutional treatment. In strumous subjects, a sprain may lead to the development of very serious inflammations.

Muscles that have been sprained sometimes undergo a species of rigid atrophy, with much impairment of motion of the limb or joint. In such cases, frictions, douches, and above all, electricity, will be found useful.

RUPTURE OF THE SHEATH.—It occasionally happens that the sheath is ruptured, so that the belly of the muscle forms a kind of hernial protrusion through the aperture. This usually happens with the biceps, or the extensors of the fingers or the rectus femoris.

DISLOCATION OR DISPLACEMENT OF MUSCLES OR TENDONS.—The long slender muscles of the forearm, and the complicated ones of the back with their innumerable tendons and bellies, and all tendons lying in grooves in bones, are liable to be displaced by some sudden and unusual movement. The accident is popularly spoken of as a "rick." The characteristic features of the accident are, that during some forcible movement the patient feels a sudden severe pain, localized to a single spot, and at the same time finds himself unable to execute certain movements. The Surgeon in the majority

of cases by careful examination and by noting exactly what movement causes the pain, will be able to ascertain which is the affected muscle. A displaced superficial tendon may be felt moving in its abnormal situation. Callender laid down the following rules for the treatment of this injury. First, guided by the pain, decide as to the muscle, or digitation of a muscle, which is probably the seat of the injury. Secondly, relax the muscle as far as possible by putting the part in the position which would be induced by its full contraction. Thirdly, by firm manipulation, such as by rubbing with the hand, or by kneading with the thumb, endeavour to replace it. Fourthly, if this fail, make pressure over the part whilst you make the patient contract the muscle, or if he cannot do this, put the part suddenly in such a position as to stretch the muscle. These manipulations must be done without an anæsthetic, as we need guidance from the sensations of the patient and the action of the affected muscle. Replacement is seldom possible after two or three weeks. If the condition is left unrelieved the parts seem to accommodate themselves to their new positions, and the pain subsides, but some permanent weakness may remain. The accident is always likely to recur, even if the displacement has been successfully reduced.

The following are the chief situations in which this accident has been met with :

The Long Tendon of the Biceps. In a case of this kind described by Callender, there was great pain and inability to move the biceps or even the shoulder-joint. The shoulder seemed to droop forwards. The tendon could be felt lying at the inner side of its groove. It could be replaced, but no treatment would keep it in position. It is probable that some at least of the cases of so-called subluxation of the shoulder have been examples of the injury.

Various Tendons at the Wrist have been displaced. They are usually replaced without difficulty by the means above described. The parts must be kept fixed for about two weeks, by means of splints and properly arranged padding.

The Small Muscles of the Back, or of the back of the neck, are occasionally displaced. Replacement can best be effected by firm pressure over the painful spot, while the patient carries out the movement that gives him pain.

The Tendon of the Peroneus Longus may slip out of its sheath behind the outer ankle, which is torn in some violent twist of the foot inwards. The accident is liable to recur, and is often a source of much discomfort and temporary lameness. The treatment consists in the first instance of absolute fixation of the foot for some weeks in plaster bandages or splints, to give time for the sheath to consolidate. To prevent recurrence, a spring clip should be worn, so as to press the tendon against the fibula.

Rupture and Division.—Subcutaneous rupture of muscles and tendons not unfrequently occurs, not so much from any external violence as from the contraction of the muscle rupturing its own substance. The rupture may occur at one of four points : in the muscular substance itself ; at the line of junction between the muscle and the tendon ; through the tendon ; and, lastly, at the point of insertion of the muscle or tendon into bone. Scudder found that, in 21 cases, the rupture occurred at the point of origin of the tendon from the muscle 13 times ; and in the remaining 8, the muscle itself was torn.

These ruptures most commonly occur in middle-aged or elderly men, who have lost the elasticity of youth, though their physical strength is unimpaired. At the moment of rupture, the patient usually experiences a sudden shock, as if he had received a blow, and sometimes hears a snap. He becomes unable to use the injured limb, and at the part where the rupture has occurred he finds a hollow or pit, produced by the retraction of the ends of the torn muscle, the belly of which contracts into a hard lump.

These accidents, though troublesome, are seldom serious. The tendo Achillis, the quadriceps extensor of the thigh, the triceps of the arm, the biceps, the deltoid, the rectus abdominis, are the tendons and muscles that most commonly give way, the relative frequency being indicated by the order in which they are here placed.

Muscles and tendons may be cut across accidentally or purposely in almost any part of the body. In these injuries there is always a considerable amount of gaping of the wound, owing to the retraction of both ends, if a muscle be divided, and of the muscular end only, if a muscle be separated from its tendon or the tendon cut across.

Union.—The mode of union of these injuries has been well described by Paget. When a tendon is cut across, the space between the ends is immediately filled by a blood-clot. Exudation rapidly follows from the vascular sheath and areolar tissue in the neighbourhood: the clot is penetrated by the wandering cells, and is soon decolorized and absorbed, till on the third day its place is occupied by a soft greyish-pink mass, extending also into the sheath and surrounding the cut ends of the tendon. This mass will be found to be composed of small round cells, with a homogeneous intercellular substance, mixed with which may here and there be seen some remains of the blood clot. New vessels penetrate it from without, and it afterwards undergoes the ordinary changes observed in the development of granulation-tissue into fibrous tissue. By experiments upon animals, Paget showed that by about the fourth or fifth day the bond of union has become more defined in outline, and forms a distinct cordlike mass between the ends of the tendon, and the microscope shows that the cells have lengthened out and become spindle-shaped, so that the tissue appears fibrillated: in the course of two or three more days it becomes tough and filamentous: after this the tissue gradually perfects itself, until it closely resembles normal tendon, though for some time it remains dull white and more cicatricial in appearance. The strength of this bond of union is marvellously great: Paget found that the tendo Achillis of a rabbit, six days after its division, required a weight of 20 lbs. to rupture it. In ten days the breaking weight was 56 lbs. Divided muscles unite in the same way as tendons but less quickly, and by a fibrous cicatrix; Weber, Gussenbauer and others have, however, recorded observations which tend to show that, under favourable conditions, gradual regeneration of muscular tissue may take place in the scar.

Treatment.—The principle of treatment in these cases when the injury is subcutaneous is extremely simple: it consists in relaxing the muscles by position, so as to approximate the divided ends; and in maintaining the limb in this position for a sufficient length of time for union to take place. If muscular relaxation be not attended to, the uniting bond will be elongated and weak, and perhaps altogether inefficient. Stiffness and weakness are often left for many months after union has taken place; very commonly,

INJURIES OF SPECIAL MUSCLES AND TENDONS.

When the **tendo Achillis** is ruptured, the best mode of
treatment consists in the application of an apparatus
formed of a dog-collar placed round the thigh above the
knee, from which a strap is attached to a loop in the
back of a slipper: by shortening this strap, the leg is
bent on the thigh, and the foot extended, so that the
muscles of the calf become completely relaxed (Fig. 116).
After this simple apparatus has been used for about
three weeks the patient may be allowed to go about
wearing a high-heeled shoe for some weeks longer.

Partial Rupture of the Muscles of the Calf.

This injury has received the name of *Latent Tissue*
by the frequency with which it occurs amongst middle-aged
men during that game. It consists of a rupture of some of the
fibres of the gastrocnemius, usually near their attachment to the tendo
Achillis. The patient feels a sudden pain, so that he may think he has been struck
by a ball, and finds he cannot use his leg. Sometimes a small swelling
may be felt at the seat of the rupture. On the following day the calf is more
discoloured by extravasated blood. The treatment recommended by
Wharton Hood is to elevate the limb for a few minutes, and then to strap the
leg in the same way as for a chronic ulcer. The strapping must not be too
tightly applied at first. On the third day it may be removed and reapplied
more firmly, and this must be repeated at intervals of two or three days for
about two weeks. The patient may move about during the treatment, but
must avoid violent exercise.

The **Quadriceps Extensor of the Thigh** may be torn away from its
insertion into the patella, or the tendon of the rectus may be ruptured about
an inch above this. Such an accident occurs in the same way that the patella
is broken across, namely, by a violent muscular effort to prevent falling while
the knee is semi-flexed. Under these circumstances one of three things may

happen: the tendon of the rectus, the patella, or the ligamentum patellæ will give way. Most commonly the patella is broken across; next the tendon gives way, and least frequently the ligament. When the tendon gives way the patient falls on the ground, is unable to raise or stand on the injured limb, and a distinct gap occasioned by the retraction of the muscle can be felt above the patella between the fleshy masses of the vasti, which are very rarely torn. The accident is usually followed by some swelling of the joint. Owing to the distance to which the upper end of the torn tendon is retracted, union may fail to take place, but even if this does occur, the attachments of the vasti remaining intact, the patient suffers but little inconvenience.

The ligamentum patellæ is rarely ruptured, and in many apparent cases of this kind a more careful examination shows that a small fragment of the patella remains attached to the ligament, and that the injury is in reality a fracture of the patella. In many recorded cases the ruptured ligament fails to unite, a wide gap being left, and the utility of the limb is seriously impaired.

The **Treatment** both of rupture of the tendon and of the ligament is the same as that of fractured patella, viz. elevation of the limb, supported on a back splint in the extended position of an angle of about 135° with the body. This must be continued for several weeks, when the patient may be allowed to get about with the joint protected by a knee-cap. In three or four cases of this accident which I have seen, somewhat troublesome stiffness of the parts has long been left. If the ruptured ligamentum patellæ fails to unite and a useless limb is left, the two ends may be exposed by a longitudinal incision, and sutured together after having been freshened. Sands, of New York, has successfully performed this operation in a case which came under his care eight months after the accident. He used silver sutures, which were left in the wound. The ends of the ruptured ligament could be brought together only after several transverse incisions had been made subcutaneously in the quadriceps above the knee.

An accident well known to football players as "*the poop*" is most commonly caused by a blow on the front of the thigh. There is a feeling of helplessness in the limb, which soon passes off, so that the player can resume the game. Slight lameness follows, with localized tenderness in the extensor muscles of the knee. The treatment consists in strapping the part, and recovery is soon complete. The exact nature of the injury is doubtful, but probably some muscular fibres are ruptured or a partial paralysis is produced by the blow.

Rider's Sprain may occur in two situations—in the adductors, and in the internal rotators of the femur. It is more commonly met with in the adductors. It consists in a laceration of some of the muscular fibres or of the fascia covering the muscles. It is due to a violent or spasmodic contraction of these muscles when the rider is in danger of losing his seat. The pain is very great. The grip is lost, and the sufferer is unable to ride. When the internal rotators, or some of the capsular muscles of the hip-joint, are the seats of the sprain, the pain and disability are referred to the back of the seat.

The *treatment* consists in rest, and the use of a spica strap or bandage, with a pad over the injured muscle, so as to compress it and control its action.

Laceration of the Rectus Abdominis Muscle may occur in the effects of childbirth, or from blows upon the abdominal wall; a ventral hernia being

New York, removed a section of the whole brachial plexus of the nerves from the spinal column. This was done in a lad whose right arm had been seriously injured in firing a salute, amputated, but the patient suffered the most agonizing torture from nerve-lesion high up in the limb. So great were his sufferings that he was uncontrollable in his actions, and, although perfectly sane, gave the most intense excitement. The operation consisted in making an incision along the outer border of the right sterno-mastoid, and a flap was turned down following the line of the clavicle. The J-shaped flap was turned up beneath and its contents carried to one side, and the brachial

exposed. Pieces fully a quarter of an inch in length were cut from the four lower cervical and first dorsal nerves, and from one of the lower limbs was taken. Considerable relief from suffering followed the operation.

3. **Nerve-stretching.**—This operation was introduced by N. S. Paine, of New York, as a mode of treating intense neuralgia following injury. In a case of neuralgia affecting the arm, and resulting from gunshot injury, he stretched the ulnar nerve, then the nerves surrounding the arm, and lastly, the brachial plexus itself. The result was a permanent cure. Since then the operation has been extensively practised.

Under the name of "nerve-stretching" two distinct operations are performed. In operating on the larger trunks the nerve is exposed, cleared of its sheath an inch or more, and forcibly stretched either by passing the

the case of the sciatic, or by means of a hook : but on account of the great strength of the nerve its power of conduction is never completely lost, even if considerable force be used, although there may be some alteration in its function. In operations on the smaller nerves, as the facial, the nerve is exposed and stretched with a hook, and it will always be found, that moderate force be used, that conducting power is as completely abolished as if the nerve had been divided. This operation is therefore equivalent to division, the only difference being that, as the continuity of the nerve is not broken, restoration of function is certain to take place sooner or later.

The most complete account of nerve-stretching in the English language is given by Marshall in the Bradshaw Lecture delivered at the Royal College of Surgeons in 1883, to which the reader is referred for fuller information on the subject.

Nerves possess but slight extensibility and elasticity, but their cohesion or strength is very great. The breaking-strain of a nerve varies necessarily with its size. Thus that of the supra-orbital is said to be about six pounds, and a healthy sciatic will support 1·8 of the weight of the body, or in a heavy man about 270 lbs. When a nerve is steadily stretched longitudinally with moderate force, the strain is borne at first almost entirely by the fibrous sheath composing the sheath. The nerve-fibres are straightened and the spaces between them narrowed, and thus the vessels and lymph-spaces could be squeezed and emptied of their contents. When the strain is increased to two-thirds of the breaking-strain and continued for some minutes, it begins to act more directly on the tubules, and produces very definite changes in their structure. The first effect observed is fissuring or cleavage of the outer sheath. A still more forcible strain causes the medullary sheath to break up into irregular masses. If still greater force be applied the axis-cylinder and the tubular sheath may be ruptured. This degree of injury can be inflicted in actual practice when stretching a large nerve by longitudinal traction with the finger and thumb. In stretching a nerve transversely with a hook the medullary sheaths are commonly ruptured and displaced at the point of pressure, and the axis-cylinder ruptured, the continuity of the nerve being thus practically interrupted.

The rationale of the effects of nerve-stretching for the relief of chronic neuritis was first suggested by Marshall. The fact that in neuritis the nerve is tender, and that, as a rule, the pain is not referred to the parts supplied by the affected nerve, led him to the conclusion that the nerve-trunks must contain sensory fibres distributed in their sheaths, or *nervi nervorum*. At the time this suggestion was made, although sympathetic fibres accompanying blood vessels had been demonstrated in nerves by Sappey, no others had been described. Victor Horsley, following up Marshall's suggestion, has, however, shown that short medullated fibres terminating in tactile corpuscles are present in the perineurium and epineurium of all nerves. The pain and tenderness of the nerves in neuritis may, therefore, be explained by the pressure on these *nervi nervorum* by inflammatory exudations and new connective tissue.

In stretching a nerve the strain is first borne by the sheath, and it is not until very considerable force is applied that the proper tubules of the nerve begin to suffer. It is easy to understand, therefore, how the *nervi nervorum* ramifying in the sheath may be strained or ruptured to such an extent as to destroy their conducting power, and thus render the nerve itself

insensible without abolishing the power of the nerve to transmit sensory and motor impulses through its proper tubules.

The *secondary effects of nerve-stretching* are the same as those of other injuries of nerves. If force sufficient to disintegrate the medullary sheath and to interrupt the conductivity of the nerve is used, the degenerative changes already described as occurring after section of a nerve take place.

The Operation of Nerve-Stretching.—The nerve is exposed by an incision parallel to its course, unless this would needlessly damage neighbouring parts. It must be separated cleanly from the fat and areolar tissue surrounding it for a sufficient distance, and then raised from its bed with a blunt hook or with the fore-finger. If the nerve be of sufficient size it is seized between the finger and thumb and steady traction made upon it, as much as possible in the direction of its course. It should be stretched both centrifugally and centripetally, and the traction should be maintained for about five minutes in each direction. In the case of a small nerve, such as one of the branches of the fifth or the facial, two hooks are passed beneath, which are then separated from each other with sufficient force thoroughly to stretch the trunk without actually tearing it across. The force to be used necessarily varies with the size of the nerve. The sciatic may safely be stretched with a force of thirty pounds, which is about as much as can be exerted when grasping the nerve between the finger and thumb. In a fresh dead dog the head may be raised by a hook under the facial nerve without tearing it across, but a smaller degree of force must be used in operating on the living body. The Surgeon must use his judgment in the force he employs in stretching the various nerves. The after-treatment of the wound presents nothing peculiar, but every effort should be made to secure union by the first intention, otherwise the operation may serve as a starting-point for neuritis.

Bloodless nerve-stretching has been suggested in the case of the sciatic. This is done by flexing the thigh upon the abdomen while the knee is bent. The leg is then gradually but forcibly extended. In this position the sciatic nerve is thoroughly put on the stretch.

Physiological Effects of Nerve-Stretching.—It may at once be stated that the effect of stretching a small nerve on a blunt hook, even if only a moderate degree of force be used, is completely to interrupt its physiological continuity, abolishing sensation or voluntary motion or both, according to the nature of the nerve, in the parts supplied by it. In the case of a larger nerve stretched between the finger and thumb, a slight stretching seems to increase its conducting power to sensory and motor impulses of all kinds. A stronger pull impairs the function of the sensory fibres, causing numbness, or even complete anaesthesia, and if still more force be used motor paralysis may be induced. There is no conclusive evidence that nerve-stretching, however forcible, produces any mechanical or functional effect on the nerve-centres.

Results.—Nerve-stretching has been employed in a great variety of cases besides cases of true neuritis, and these will be referred to in subsequent chapters. Marshall gives a table of 512 cases, collected from various sources. In 154 of these the operation was performed for neuralgia of the upper or lower limb, and were probably cases of true nerve-stretching without interruption of the physiological continuity of the nerve. In 108 the operation resulted in a cure, in 26 it gave rise to permanent improvement, in 115 temporary relief, and in 9 it failed, and one of these terminated in the death

patient. Nerve-stretching seems, therefore, in these cases to be very useful, and as it is practically free from danger it should always be tried when milder means have failed.

INJURIES OF MUSCLES AND TENDONS.

CONTUSIONS.—Muscles are frequently bruised by violent blows or falls, a vessel being often ruptured. The chief signs of this injury are a sense of tenderness to use the muscles, and great pain on attempting to do so. There is tenderness on pressure over the bruised spot, but passive movements do not cause pain so long as they do not put the injured fibres on the stretch. By attention to these points, it is easy to distinguish these injuries from those of neighbouring bones, which they sometimes resemble—especially in the neighbourhood of the shoulder-joint.

SPRAINS OR STRAINS of muscular parts, without rupture of fibres, are of very frequent occurrence, especially about the shoulder, the hip, and the loins, and are accompanied by much pain and stiffness, and by inability to move the part. When they occur in rheumatic subjects, these injuries not uncommonly give rise to severe and persistent symptoms; painful atrophy, rigidity, or paralysis of the injured muscle being induced in some cases. It is then difficult to determine how much is due to the direct strain of the muscle, and how much to chronic neuritis resulting from a simultaneous injury of the nerves. When complete atrophy of a muscle preceded by much pain follows a strain, it is probable that the nerves have been implicated in the injury.

THE TREATMENT of these accidents, when recent, it will be found that friction or rubbing the part with a stimulating embrocation gives relief, but, if the pain be severe, the application of hot fomentations with rest is more beneficial. In the later stages, blisters applied to the points at which the pain is most severely felt are often beneficial. If the injury occur in persons of a rheumatic diathesis, the effects are much more severe and persistent than in those who are otherwise constituted. In such persons, douches, frictions, and passive motion will, after a time, be necessary, together with proper constitutional treatment. In strumous subjects, a sprain may lead to the development of very serious inflammations.

Muscles that have been sprained sometimes undergo a species of rigid atrophy, with much impairment of motion of the limb or joint. In such cases, frictions, and, and above all, electricity, will be found useful.

PROTRUSION OF THE SHEATH.—It occasionally happens that the sheath is so displaced, so that the belly of the muscle forms a kind of hernial protrusion through the aperture. This usually happens with the biceps, or the extensors of the fingers or the rectus femoris.

LOCATIONS OR DISPLACEMENT OF MUSCLES OR TENDONS.—The long muscles of the forearm, and the complicated ones of the back with innumerable tendons and bellies, and all tendons lying in grooves in the bone are liable to be displaced by some sudden and unusual movement. The injury is popularly spoken of as a "rick." The characteristic features of the accident are, that during some forcible movement the patient feels a severe pain, localized to a single spot, and at the same time finds himself unable to execute certain movements. The Surgeon in the majority

of cases by careful examination and by noting exactly what movement causes the pain, will be able to ascertain which is the affected muscle. A displaced superficial tendon may be felt moving in its abnormal situation. Callender laid down the following rules for the treatment of this injury. First, guided by the pain, decide as to the muscle, or digitation of a muscle, which is probably the seat of the injury. Secondly, relax the muscle as far as possible by putting the part in the position which would be induced by its full contraction. Thirdly, by firm manipulation, such as by rubbing with the hand, or by kneading with the thumb, endeavour to replace it. Fourthly, if this fail, make pressure over the part whilst you make the patient contract the muscle, or if he cannot do this, put the part suddenly in such a position as to stretch the muscle. These manipulations must be done without an anæsthetic, as we need guidance from the sensations of the patient and the action of the affected muscle. Replacement is seldom possible after two or three weeks. If the condition is left unrelieved the parts seem to accommodate themselves to their new positions, and the pain subsides, but some permanent weakness may remain. The accident is always likely to recur, even if the displacement has been successfully reduced.

The following are the chief situations in which this accident has been met with :

The Long Tendon of the Biceps. In a case of this kind described by Callender, there was great pain and inability to move the biceps or even the shoulder-joint. The shoulder seemed to droop forwards. The tendon could be felt lying at the inner side of its groove. It could be replaced, but no treatment would keep it in position. It is probable that some at least of the cases of so-called subluxation of the shoulder have been examples of the injury.

Various **Tendons at the Wrist** have been displaced. They are usually replaced without difficulty by the means above described. The parts must be kept fixed for about two weeks, by means of splints and properly arranged pads.

The Small Muscles of the Back, or of the back of the neck, are occasionally displaced. Replacement can best be effected by firm pressure over the painful spot, while the patient carries out the movement that gives him pain.

The Tendon of the Peroneus Longus may slip out of its sheath behind the outer ankle, which is torn in some violent twist of the foot inwards. The accident is liable to recur, and is often a source of much discomfort and temporary lameness. The treatment consists in the first instance of absolute fixation of the foot for some weeks in plaster bandages or splints, to give time for the sheath to consolidate. To prevent recurrence, a spring clip should be worn, so as to press the tendon against the fibula.

Rupture and Division.—Subcutaneous rupture of muscles and tendons not unfrequently occurs, not so much from any external violence as from the contraction of the muscle rupturing its own substance. The rupture may occur at one of four points: in the muscular substance itself; at the line of junction between the muscle and the tendon; through the tendon; and, lastly, at the point of insertion of the muscle or tendon into bone. Scudler found that, in 21 cases, the rupture occurred at the point of origin of the tendon from the muscle 13 times; and in the remaining 8, the muscle itself

was torn.

the unaffected muscles of the limb, or from shortening of the paralyzed and atrophied muscles, should their points of attachment be approximated by the position in which the limb is placed.

The division of a purely *sensory nerve*, such as a branch of the fifth, completely abolishes sensation in the part supplied by it, but does not necessarily cause any serious disturbance of nutrition. This is probably due to the free communication between the various nerves of the face. Arloing and Tripier have shown by experiment that, after the division of a superficial sensory nerve, the neighbouring cutaneous nerves which communicate with the terminal branches of the one divided rapidly assume its functions so that sensibility may return in a few days without repair of the divided nerve. If the whole trunk of the fifth nerve is destroyed together with the Casserian ganglion, serious interference with nutrition follows, such as ulceration of the cornea or of the nasal mucous membrane. In central disease affecting the fifth nerve, the ganglion remaining intact, trophic changes do not occur, although, from loss of sensibility, the parts supplied by it are prone to suffer from injury. It may, in fact, be stated as a general rule that grave trophic changes do not occur unless a part is completely cut off from all communication with a healthy nerve-centre.

After the division of a *mixed nerve*, such as the ulnar, the nutrition of the part supplied by it is seriously modified. The muscles, as before stated, degenerate and waste. The whole part supplied by the injured nerve becomes congested, bluish, and, after a temporary rise of temperature in some cases, colder than natural. The fall of temperature is often very marked. Thus, I found in a woman who was under my care for a wound of the forearm, in which the ulnar nerve had been divided, that, twenty-one days after the injury, the temperature between the ring and the little finger of the injured side was 9° Fahr. below that of the same spot on the opposite hand. Sometimes the part becomes oedematous; the skin often becomes rough and peels, but more commonly it is smooth, red and shining—the “glossy skin” of Paget; the nails grow badly, and are brittle or scaly, and abnormally curved longitudinally. Gradually increasing stiffness, with sometimes painful swelling, of one or more of the joints of the fingers may occur. Blebs, the contents of which become purulent, not uncommonly form on the tips of the fingers. Chilblains are readily produced by slight exposure to cold, and they frequently become vesicular or slough, leaving sluggish and unhealthy ulcers. Wounds in such parts heal badly, and are peculiarly prone to be affected by unhealthy spreading inflammations. If the patient be a growing child, the development of the affected part will be more or less completely arrested.

If union takes place between the opposite ends of the divided nerve, the various phenomena that have just been described gradually disappear, and complete restoration, first of sensation and afterwards of motion, with a return to the normal nutrition of the part, eventually takes place. Some voluntary motion usually returns in the muscles before electrical irritability is re-established. In many cases, however, especially if a piece of the nerve have been removed, or if the wound in which it has been divided heal by the second intention, recovery fails to take place. Under these circumstances, the central end becomes bulbous, just as in similar conditions in stumps, and it may then become the seat of intense neuralgic pains darting downwards to

owing to the adhesion of the divided tendon to its sheath, and of the tendon to its neighbouring soft structures. Warm sea-water douches, followed by mechanical friction, will greatly tend to restore the suppleness of the parts. If stiffness does not readily yield to milder treatment, the adhesions must be broken down by forcible movement of the part under an anæsthetic. By the end of one month after the injury there will be no fear of tearing through the bond of union while so doing.

Tendons or muscles divided in an open wound must be treated by immediate suture. Either chronic catgut or antiseptic silk sutures may be used, the former being preferable; the wound should be closed over them, the leg placed in such a position as to relax the tendon, and every effort made to obtain union by the first intention. If suppuration takes place between the ends of a divided tendon, the bond of union, if any is developed, is almost always imperfect, and the divided ends form firm adhesions to the surrounding parts. Should pus form in the wound, there is great risk of its burrowing widely to the sheath, or in the loose areolar tissue surrounding the divided tendon, an accident which may be followed by sloughing of the tendon, or at least by extensive and dense adhesions.

Fig. 136.—Strap for Supporting the Leg in a Rupture of the Tendo Achillis.

INJURIES OF SPECIAL MUSCLES AND TENDONS.—When the **tendo Achillis** is ruptured, the best mode of treatment consists in the application of an apparatus formed of a dog-collar placed round the thigh above the knee, from which a strap is attached to a loop in the back of a slipper; by shortening this strap, the leg is bent on the thigh, and the foot extended, so that the muscles of the calf become completely relaxed (Fig. 136). After this simple apparatus has been used for two or three weeks the patient may be allowed to go about, wearing a high-heeled shoe for some weeks longer.

Partial Rupture of the Muscles of the Calf.

This injury has received the name of *Latens Tendo Leg*, from the frequency with which it occurs amongst middle-aged gentlemen during that game. It consists of a rupture of some of the fibres of the gastrocnemius, usually near their attachment to the tendon. The patient feels a sudden pain, so that he may think he has been struck with a ball, and finds he cannot use his leg. Sometimes a small swelling may be felt at the seat of the rupture. On the following day the calf is more or less discoloured by extravasated blood. The treatment recommended by Wharton Hood is to elevate the limb for a few minutes, and then to strap the leg in the same way as for a chronic ulcer. The strapping must not be too tightly applied at first. On the third day it may be removed and re-applied more firmly, and this must be repeated at intervals of two or three days for about two weeks. The patient may move about during the treatment, but must avoid violent exercise.

The **Quadriceps Extensor of the Thigh** may be torn away from the insertion into the patella, or the tendon of the rectus may be ruptured about an inch above this. Such an accident occurs in the same way that a patella is broken across, namely, by a violent muscular effort to prevent falling when the knee is semi-flexed. Under these circumstances one of three things will

TREATMENT OF INJURIES CAUSING INTERRUPTION OF THE CONDUCTING POWER OF A NERVE.—The treatment of these injuries may be divided into two parts: 1st, the *Local treatment of the Injured nerve*, and 2dly, the *Treatment of the Paralysed part*.

1. The **Local Treatment**.—In cases of *subcutaneous injury* nothing should be done, for it may be taken for granted that, although the nerve may be completely paralysed, its continuity is not destroyed. On dissecting limbs amputated for the most severe railway or machinery accidents, the nerves are almost invariably found untorn in the midst of the crushed tissues. To cut down, therefore, in a subcutaneous injury with the intention of suturing the nerve would be a grievous error. When the function of the nerve is abolished by pressure, the cause of pressure must be removed if possible, as by the cure of an aneurism, the excision of a tumour, or the reduction of a dislocation. When the cause of the paralysis is the *implication of the nerve in a cicatrix or in the callus of a fracture*, nothing should be done locally until, after waiting many months, it becomes evident that nature will not effect a cure. It will very rarely be found necessary in such cases to adopt any operative plan of treatment, the symptoms disappearing as the scar becomes looser with age, or as the provisional callus of the fracture is absorbed. Warren, however, relieved a case of neuralgia resulting from implication of a nerve in cicatricial tissue by dissecting it out without dividing or otherwise injuring it.

Primary Suture.—In cases of *division of a nerve in an open wound* no doubt exists as to the proper line of treatment: the two ends of the nerve should be found and carefully secured to each other by fine sutures. The best material for suture is very fine chromic catgut. Silk, which would not be absorbed for many weeks, might cause irritation and possibly severe neuralgia. The needle should be a common round sewing needle, which, if necessary, can be bent into a curve in the flame of a spirit-lamp and hardened again by being dipped in cold water; the ordinary flat surgical needle, with its cutting edges, needlessly damages the nerve. The end of the nerve should not be pinched with the forceps, as this may prevent rapid union. The sutures should be passed completely through the nerve, not through the sheath only, as this ensures better approximation of the ends. Three or four sutures having being applied, according to the size of the nerve, the wound must be closed and treated by some antiseptic method if possible; suppuration being usually fatal to success. The limb must be put in such a position as completely to relax the nerve. In a large proportion of the cases union will be obtained, with restoration of function.

The *prognosis* after primary nerve suture is good, but the period at which restoration of function may be expected varies greatly. Reference has already been made to these exceptional cases in which a rapid return of function has suggested the occurrence of primary union. Bowlby concludes from the consideration of a large number of cases that recovery may occur after weeks, months, or years: he finds that improvement usually begins within a year, but that a case cannot be looked upon as quite hopeless until the lapse of two or three years.

Secondary suture may be undertaken if the primary operation has failed, or if no attempt was made to suture the nerve at the time of the injury.

The operation is performed by freely exposing the nerve after rendering the limb bloodless. Its proximal extremity can sometimes be found by its bulbous

the consequence. Guthrie relates several remarkable cases occurring in military practice, of progressive atrophy of a part of the muscular wall of the abdomen following blows.

In **Rupture of the Muscles or Tendons of the Arms or Shoulder** support in a sling is all the special treatment needed. When the muscles

Fig. 157. Atrophy of Capsular Muscles of Shoulder

about the shoulder are the seat of injury, rapid atrophy is apt to ensue, probably owing to the implication of the circumflex and suprascapular nerves, and consequent interference with the nutrition of the part. Fig. 157 is a good illustration of the remote effects of such a strain of the capsular muscles of the shoulder-joint. In this case the accident was caused by severe dragging upon the arm by the reins of a runaway horse.

In division of the **Extensor Tendons of the Fingers**—a very common accident—the tendons should, if possible, be united with catgut or tendon sutures, and the hand must be kept extended on a straight splint for three weeks until perfect union has taken place.

The **Flexor Tendons** of the hand may also be divided, either on the fingers or in the palm. In these cases the tendons should, if possible, be sutured, after which the fingers and wrist must be flexed and fixed on a suitable splint. Extensive retraction of the upper ends of the tendons often occurs, so that they can only be reached by carefully enlarging the wound upwards with strict antiseptic precautions.

Should the first operation fail, or should the division of the tendon have been overlooked at the time of the injury, secondary suture may be performed after the wound has healed.

In a case recorded by Mayo Robson, four and a half inches of the flexor tendon of a hopelessly smashed middle finger were successfully used to replace the tendon of the extensor indicis which had been torn away by the same injury.

CHAPTER XIX.

INJURIES OF BONES AND JOINTS.

INJURIES OF BONES.

A BONE may be bruised, bent, cut, or fractured.

Bruising of the Bone and Periosteum is usually of no great moment, but where the bone is but thinly covered, as at the shin or elbow, it may give rise to troublesome symptoms from inflammation of the periosteum, especially in gouty or syphilitic subjects. If the contusion be severe, the vitality of a layer of the bone may be destroyed, as happens sometimes from the graze or contusion of a bullet; whilst in certain cases a bruise of the bone is followed by acute suppuration beneath the periosteum or by tuberculous disease. In old people, the contusion of a bone may be followed by atrophy and shortening, as happens in the neck of the femur.

In the *Treatment* of bruised bone, immediate relief may be afforded by leeches, fomentations, or the application of warm lead and opium lotion. At a later period, and more especially if the pain be severe at night, iodide of potassium may be useful. In gouty subjects colchicum with salines will usually give relief. There is a very troublesome condition following a graze of the shin, with bruise of the periosteum and tibia, in which the slight abrasion does not heal readily, and the periosteum becomes thickened and pulpy. In these cases, rest of the limb, the application of lead lotion, the support of a bandage, and the administration of the iodide with bark, will be found to afford great relief. The consequences of bruise will be considered when we come to speak of necrosis.

Bending of Bone may occur in two conditions, viz. without or with fracture. Bending without fracture is met with in very young subjects, before the completion of ossification. When it takes place in adult life, it is the result of some structural change, by which the natural firmness of the osseous tissue is diminished. The bending most commonly occurs in the long or slender bones, especially the clavicle, the radius and the femur, but sometimes is met with in the flat bones, or those of the skull, in which depression takes place from a blow without fracture having occurred. In many cases of bending both of long and of flat bones, there is partial fracture on the convex side—the “green-stick fracture” (see p. 521).

The *Treatment* is simple: the Surgeon gradually straightens the bone, by applying a splint on its concave side, towards which the bone is pressed by a bandage and a pad applied upon its greatest convexity.

Fractures will be described in the two following chapters.

INJURIES OF JOINTS.

CONTUSIONS.—Joints are often *contused* by kicks, falls, or blows, so as to be severely injured, giving rise to much pain, and consecutive inflammation of

the consequence. Guthrie relates several remarkable cases occurring in military practice, of progressive atrophy of a part of the muscular wall of the abdomen following blows.

In **Rupture of the Muscles or Tendons of the Arms or Shoulder** support in a sling is all the special treatment needed. When the muscles

Fig. 157. Atrophy of Cervical Muscles of Shoulder.

about the shoulder are the seat of injury, rapid atrophy is apt to ensue, probably owing to the implication of the circumflex and suprascapular nerves, and consequent interference with the nutrition of the part. Fig. 157 is a good illustration of the remote effects of such a strain of the capsular muscles of the shoulder-joint. In this case the accident was caused by severe dragging upon the arm by the reins of a runaway horse.

In division of the **Extensor Tendons of the Fingers**—a very common accident—the tendons should, if possible, be united with catgut or tendon sutures, and the hand must be kept extended on a straight splint for three weeks until perfect union has taken place.

The **Flexor Tendons** of the hand may also be divided, either on the fingers or in the palm. In these cases the tendons should, if possible, be sutured, after which the fingers and wrist must be flexed and fixed on a suitable splint. Extensive retraction of the upper ends of the tendons often occurs, so that they can only be reached by carefully enlarging the wound upwards with strict antiseptic precautions.

Should the first operation fail, or should the division of the tendon have been overlooked at the time of the injury, secondary suture may be performed after the wound has healed.

In a case recorded by Mayo Robson, four and a half inches of the flexor tendon of a hopelessly smashed middle finger were successfully used to replace the tendon of the extensor indicis which had been torn away by the same injury.

CHAPTER XIX.

INJURIES OF BONES AND JOINTS.

INJURIES OF BONES.

A BONE may be bruised, bent, cut, or fractured.

Bruising of the Bone and Periosteum is usually of no great moment, but where the bone is but thinly covered, as at the shin or elbow, it may give rise to troublesome symptoms from inflammation of the periosteum, especially in gouty or syphilitic subjects. If the contusion be severe, the vitality of a layer of the bone may be destroyed, as happens sometimes from the graze or contusion of a bullet; whilst in certain cases a bruise of the bone is followed by acute suppuration beneath the periosteum or by tuberculous disease. In old people, the contusion of a bone may be followed by atrophy and shortening, as happens in the neck of the femur.

In the *Treatment* of bruised bone, immediate relief may be afforded by leeches, fomentations, or the application of warm lead and opium lotion. At a later period, and more especially if the pain be severe at night, iodide of potassium may be useful. In gouty subjects colchicum with salines will usually give relief. There is a very troublesome condition following a graze of the shin, with bruise of the periosteum and tibia, in which the slight abrasion does not heal readily, and the periosteum becomes thickened and pulpy. In these cases, rest of the limb, the application of lead lotion, the support of a bandage, and the administration of the iodide with bark, will be found to afford great relief. The consequences of bruise will be considered when we come to speak of necrosis.

Bending of Bone may occur in two conditions, viz. without or with fracture. Bending without fracture is met with in very young subjects, before the completion of ossification. When it takes place in adult life, it is the result of some structural change, by which the natural firmness of the osseous tissue is diminished. The bending most commonly occurs in the long or slender bones, especially the clavicle, the radius and the femur, but sometimes is met with in the flat bones, or those of the skull, in which depression takes place from a blow without fracture having occurred. In many cases of bending both of long and of flat bones, there is partial fracture on the convex side—the “green-stick fracture” (see p. 521).

The *Treatment* is simple: the Surgeon gradually straightens the bone, by applying a splint on its concave side, towards which the bone is pressed by a bandage and a pad applied upon its greatest convexity.

Fractures will be described in the two following chapters.

INJURIES OF JOINTS.

CONTUSIONS.—Joints are often *contused* by kicks, falls, or blows, so as to be severely injured, giving rise to much pain, and consecutive inflammation of

the capsule, synovial membrane, or other structures entering into their formation. As a result of contusion the joint may be suddenly distended with blood—**hæmarthrosis**. The blood so effused, mixed as it always is with much synovia, undergoes absorption after a time, without leading to any inconvenience.

The **Treatment** should consist of the application of a splint to ensure complete rest. An evaporating lotion or an ice-bag may be applied over the joint. Should the amount of effusion be very considerable, the tension and pain may be at once relieved by removing the blood by means of the aspirator. The needle must be washed through several times with a 1 in 20 solution of carbolic acid before being inserted, and care must be taken to keep it perfectly steady while it is in the joint.

In some cases a **bursa**, situated in the neighbourhood of a joint, is seriously bruised, and becomes inflamed: in consequence of which suppuration may follow. When this takes place, free incision into the inflamed part, with antiseptic treatment, will afford speedy and effectual relief.

SPRAINS.—When a joint is twisted violently so that its ligaments are either much stretched or partially torn across, though there be no displacement of the osseous surfaces, it is said to be *sprained*. These injuries are exceedingly painful and troublesome in their consequences. They most frequently occur at the wrist, knee, and ankle. The pain is very severe, and often sickening. Its intensity is very remarkable in view of the low degree of sensibility possessed by ligaments in the normal state. They may be an without pain, but if stretched in a longitudinal direction or twisted, pain of the most intense character is at once set up—a wise provision of Nature guarding against articular displacements. At the time of the sprain a certain amount of blood is effused into the articular cavity and the surrounding tissues, in consequence of which the limb in a few days becomes discoloured for some distance above and below the joint. The sprain is rapidly followed by swelling and inflammation of the joint and investing tissues, often very chronic and tedious. As the inflammation subsides, stiffness and pain in using the part continue for a considerable length of time, and are in some cases followed by a kind of rigidity and wasting of the limb. In individuals of a rheumatic or gouty habit of body, the inflammation of the joint consequent on the sprain is often most tedious and chronic, and will yield only to appropriate constitutional treatment, whilst in strumous subjects tuberculous disease of the joint may follow.

Treatment.—If the sprain be slight, rubbing the part with a stimulating embrocation, and giving it the support of strapping or a bandage, are all that need be done. But if it be at all severe, more active measures must be had recourse to. These must vary according to the condition of the joint when the Surgeon sees the patient: but they are all based on the principle of securing perfect rest and subduing inflammation. In the vast majority of these injuries all that is necessary is to keep the part at rest for two weeks. The amount of discoloration that often follows a sprain is sufficient evidence of the extent of the laceration of the ligaments that has taken place. For the repair of this, rest is as necessary as for the healing of an open wound or the union of a broken bone. As a rule, however, unless the Surgeon makes it impossible, the patient, finding that he can still use the joint, although with some pain, continues to do so. This is the reason that sprains are so often

of the patient. Nerve-stretching seems, therefore, in these cases to be very successful, and as it is practically free from danger it should always be adopted when milder means have failed.

INJURIES OF MUSCLES AND TENDONS.

CONUSIONS.—Muscles are frequently bruised by violent blows or falls, a few fibres being often ruptured. The chief signs of this injury are a sense of inability to use the muscles, and great pain on attempting to do so. There is tenderness on pressure over the bruised spot, but passive movements do not cause pain so long as they do not put the injured fibres on the stretch. By careful attention to these points, it is easy to distinguish these injuries from fractures of neighbouring bones, which they sometimes resemble—especially in the neighbourhood of the shoulder-joint.

SPRAINS OF STRAINS of muscular parts, without rupture of fibres, are of very common occurrence, especially about the shoulder, the hip, and the loins, and are accompanied by much pain and stiffness, and by inability to move the part. When they occur in rheumatic subjects, these injuries not uncommonly give rise to severe and persistent symptoms; painful atrophy, rigidity, or local paralysis of the injured muscle being induced in some cases. It is then often difficult to determine how much is due to the direct strain of the muscle, and how much to chronic neuritis resulting from a simultaneous strain of the nerves. When complete atrophy of a muscle preceded by much pain follows a strain, it is probable that the nerves have been implicated in the injury.

In the **Treatment** of these accidents, when recent, it will be found that kneading or rubbing the part with a stimulating embrocation gives relief, but, if the pain be severe, the application of hot fomentations with rest is more effectual. In the later stages, blisters applied to the points at which the pain is most severely felt are often beneficial. If the injury occur in persons of a rheumatic diathesis, the effects are much more severe and persistent than in those who are otherwise constituted. In such persons, douches, frictions, and passive motion will, after a time, be necessary, together with proper constitutional treatment. In strumous subjects, a sprain may lead to the development of very serious inflammations.

Muscles that have been sprained sometimes undergo a species of rigid atrophy, with much impairment of motion of the limb or joint. In such cases, frictions, douches, and above all, electricity, will be found useful.

RUPTURE OF THE SHEATH.—It occasionally happens that the sheath is ruptured, so that the belly of the muscle forms a kind of hernial protrusion through the aperture. This usually happens with the biceps, or the extensors of the fingers or the rectus femoris.

DISLOCATION OR DISPLACEMENT OF MUSCLES OR TENDONS.—The long slender muscles of the forearm, and the complicated ones of the back with their innumerable tendons and bellies, and all tendons lying in grooves in bones, are liable to be displaced by some sudden and unusual movement. The accident is popularly spoken of as a "rick." The characteristic features of the accident are, that during some forcible movement the patient feels a sudden severe pain, localized to a single spot, and at the same time finds himself unable to execute certain movements. The Surgeon in the majority

case of sprain, and will be fully considered in the chapter on Diseases of Joints.

5. In severe sprains of joints, more especially of the knee, ankle, and shoulder, it often happens that there is a *slight displacement of the articular surfaces*. This may be directly occasioned by the violence that sprains the joint, or it may be secondary, coming on at a later period, owing to the constrained position in which the injured articulation has been kept for some length of time. If allowed to remain, it seriously interferes with the free mobility of the joint. In order that this be maintained, the most accurate adaptation of the articular surfaces is necessary. If there be the very slightest deviation from the accuracy of this "fit," they become locked in movement, and all motion becomes painful. This is especially the case in the hinge-joints, as the knee and elbow. In the ball and socket joints, more especially in the shoulder, the head of the humerus is apt to be thrown very slightly forwards on to the edge of the glenoid cavity, where it becomes fixed, all movements of the joint being exquisitely painful.

In all these cases of slight displacement connected with sprains that do not amount to dislocation, but where there is only a very slight want of true coaptation between the articular surfaces, the patient should be put under anaesthesia, and the joint "wrenched," so as to replace the bones and restore freedom and ease of movement.

So also, at a later period, when after a severe sprain, a stiff, painful, and possibly slightly distorted joint is left, no time should be lost in "wrenching" it. By this means, adhesions at this stage are broken down, and the proper "fit" of the bones restored. By neglecting this very simple treatment and leaving the joint but partially and only painfully mobile, the Surgeon is much discredited, and the patient drifting into the hands of the "bone-setter," has his limb "wrenched" into utility and ease by a most simple manœuvre.

WOUNDS OF JOINTS.—A joint is known to be wounded when synovia escapes from the aperture or when the interior of the articulation is exposed. If there be any doubt as to the wound having penetrated the synovial membrane, no attempt should be made to ascertain this by probing, as in this way the very thing that is to be feared may be brought about by the Surgeon. If the wound be of sufficient size a careful and gentle examination may safely be made with the finger, after the hands have been carefully washed and disinfected. In all doubtful cases the wound must be treated as one of the joint, and the question whether it penetrated or not will often be cleared up by the symptoms that supervene.

Pathology.—In no class of injuries are the effects of the admission of air and of the consequent decomposition of the discharges more marked than in wounds of joints. The most extensive subcutaneous injuries of joints are recovered from, as a rule, without a serious symptom. Thus a simple dislocation of a large joint, although accompanied by laceration of the capsule, tearing of neighbouring muscles, and abundant extravasation of blood, is almost invariably recovered from with but little pain or inflammation, and with perfect restoration of mobility. On the other hand, a small incised wound, such as might be made by a stab with a pocket-knife, may be followed by the most severe constitutional symptoms and the most acute destructive inflammation of the joint, or, as it is called, **Traumatic Septic Arthritis**. The reason of this is not difficult to find. A joint consists in

most cases of an irregular cavity, capable of very considerable distension and very difficult to drain perfectly. A wound causes an effusion into the cavity, first of blood and, almost immediately after, of synovia, mixed with serous exudation from the vessels of the synovial membrane. The whole cavity thus becomes distended more or less tensely, according to the amount of drainage allowed by the wound, with putrescible matter, and this is brought into direct contact with the air by means of the external opening. The causes of decomposition thus being admitted, in the great majority of cases putrefaction follows, and the whole synovial membrane and the surfaces of the cartilages become bathed in septic fluid. As the result of this the most acute inflammation is set up, rapidly reaching the stage of suppuration. This soon extends to the *ligaments*, which become softened and yield, allowing the articular surfaces to become displaced; at the same time abscesses form outside the joint, either from perforation of the capsule or by extension of the inflammation through it; these may burrow widely beneath the muscles surrounding the joint. Within the joint the *cartilages* perish, in consequence of the irritation to which they are exposed; they become loosened from the subjacent bone, and by a process rather of maceration and friction than of true ulceration they become worn away at those points at which the articular surfaces have been most continuously in contact: the *bone* beneath is thus exposed, and from the combined irritation of the pressure of the opposed surfaces, a certain amount of friction, and the contact of the septic discharges, ulceration spreads rapidly into it. Thus the whole articulation becomes completely disorganized. This process is necessarily accompanied by very high fever. There is no surface in the body from which absorption takes place more rapidly than from the synovial membrane of a joint: as soon, therefore, as it becomes bathed in septic matter severe fever is developed, its intensity corresponding with the size of the joint and the extent of surface from which absorption is taking place. When the interior of the joint becomes covered by granulation-tissue, which presents a more or less efficient barrier to further absorption—that is to say, by about the eighth or tenth day—the fever subsides. Before this, however, the patient may perish from septic poisoning, or the case may become complicated by some infective process, as septic infection or pyæmia. The serious consequences, therefore, that follow wounds of joints may be traced entirely to the following causes: the accumulation of blood and serous effusion in the cavity of the joint, and the decomposition of the discharges, aggravated in some cases by want of rest and by the unhealthy constitutional condition of the patient and the bad hygienic surroundings in which he may be placed.

There are two ways, however, in which, without any special treatment, a wounded joint may escape the destructive processes above described: first, if the wound be very small and the instrument inflicting it perfectly clean, union of the external opening may take place by first intention, and the after-progress of the case may be the same as in a subcutaneous injury: secondly, if the wound be very large, so as to give perfect drainage to the cavity and thus to prevent the retention within it of decomposable matter, recovery may take place with comparatively little local inflammation or constitutional disturbance. It is a medium-sized wound, one too large or too contused to heal by the first intention and too small efficiently to drain the joint, that is the most dangerous. Wounds of joints, resulting from gun-shot injury, are necessarily the worst. In these, the aperture can rarely be closed

and united by the first intention; and the track of the ball must almost inevitably suppurate. The bones are also usually splintered, and foreign bodies of various kinds are introduced into the articulation, hence the most extensive and fatal mischief commonly ensues.

In a case of traumatic septic arthritis, if we have the opportunity of examining the joint, the appearances will vary with the time after the infliction of the injury. At the end of from twenty-four to forty-eight hours the synovial membrane will be found intensely red and injected, its surface lustreless, its fringes swollen; and the cavity will contain a quantity of turbid fluid still retaining some of the characters of synovia, but thinner than natural, in which microscopic examination would probably reveal the presence of micro-organisms. Later on, at the end of a week or ten days, the synovial membrane will have lost its characteristic appearance, being concealed by granulation-tissue, the surface of which is entirely or in part covered by a thin grey sloughing layer. The cartilages have lost their natural lustre and smoothness, their surfaces are yellowish in colour, and partial erosion will have commenced at the points at which the opposing articular surfaces have been in contact. The ligaments are swollen and softened, and the tissues surrounding the joint cedematous and infiltrated with inflammatory products. Such fluid as the joint contains will be thick pus. In the more advanced stages of the disease, when the joint has been suppurating perhaps for many weeks or even months, it will be found that it is difficult to recognize the synovial membrane, ligaments and capsule, all being lost in the mass of inflammatory products infiltrating their structures, giving them a uniform semi-transparent appearance. The cartilages are perforated in their central parts; at the circumference they have almost the appearance and feel of wet leather. The bones are exposed and are ulcerating superficially, the surface being rough and of a dark-red colour. Occasionally in the latest stages, if tolerable rest has been kept up in the treatment, granulations may have sprung up from the bony surfaces and have coalesced, and there may be some actual osseous union of the opposed surfaces. If recovery does take place in such a case it is effected by complete bony union between the opposing surfaces and gradual absorption of the inflammatory products and development of dense cicatricial tissue around the site of the joint. Microscopic examination shows nothing but the ordinary signs of inflammation in the various structures entering into the composition of the joint.

Symptoms and Effects.—The severity of the wound of a joint depends chiefly on the size of the articulation and the nature of the wound, but is also materially influenced by the age and health of the patient. Small autogenous wounds, such as are inflicted in the removal of loose cartilages, may usually be made with perfect safety, if proper antiseptic precautions be taken and the instruments be perfectly clean. But with joints laid open the result of accidents, everything depends on the prevention of septic arthritis by the establishment of good drainage and the exclusion of the causes of decomposition. This latter condition may be difficult from the presence of dirt or foreign bodies in the cavity of the joint.

If the patient escapes the dangers of septic arthritis and the wound united by the first intention, there is usually some effusion into its cavity, with heat and pain, which subside in a few days, leaving the articulation weak, tender and stiff for some considerable time. This period of swelling is one of con-

siderable anxiety to the Surgeon, but if by the third day the symptoms begin to subside, and especially if there be no marked rise of temperature, he may confidently look forward to a speedy recovery. Should septic arthritis supervene, the joint within a few hours of the infliction of the injury, swells, becomes hot and painful, and throbs. The pain steadily increases, becoming tensive and excessively severe. If the aperture be large, synovia freely escapes, which soon becomes mixed with inflammatory products. If it be small, little more than a puncture, the joint swells and fills with pus, which will either escape through the original wound or find an outlet for itself, bursting through the capsule and burrowing widely beneath the fascia of the limb before reaching the surface. The swelling at first assumes the outline of the synovial membrane, but as soon as the inflammation has extended to the ligaments it becomes globular or oval. The skin over the joint becomes red and oedematous. The limb is instinctively placed in a position of semiflexion. There are startings in the limb, worse at night, waking the patient should he fall asleep. The pain becomes agonizing should the joint be moved in the slightest degree. The constitutional disturbance becomes very severe, the temperature often rising as high as 105° Fahr. The pulse is rapid and bounding, the tongue dry, the face flushed, and there is frequently delirium at night. The patient may succumb at this stage from the intensity of the septic fever. In other cases he may be early attacked by septicæmia or pyæmia.

If the patient survive this acute period, abscesses form around the articulation, and the discharge from these, as well as from the joint, with the chronic poisoning from absorption of the products of putrefaction, may gradually prove fatal by exhaustion. Should this danger be passed through and the patient eventually survive, it will be with an ankylosed limb, the utility of which is greatly impaired.

Treatment of Wounded Joints.—The first point to be determined must be whether amputation or resection should be performed, or an attempt made to save the injured joint. If the joint have been extensively laid open, with much contusion and laceration, complicated, perhaps, with dislocation or with fracture and splintering of the bones, no attempt to save the joint is likely to succeed. In these unfavourable circumstances, however, in the upper extremity, and even in the ankle, the limb may not unfrequently be preserved. If the bones be comminuted, the removal of splinters and resection of the articular ends may advantageously be practised in many cases, more particularly if the patient be young and sound in constitution and the soft parts not too extensively damaged. But, if these be largely lacerated and widely contused, or if the patient be aged or broken in health, amputation is imperatively called for. This is especially the case when the knee is injured; extensive lacerations of the joint, if complicated with dislocation, or with comminution of the bones, being cases for immediate amputation.

In all other cases an attempt should be made to save the joint. The prognosis in cases of wounded joints has been greatly improved, and the treatment simplified, by the employment of antiseptics and drainage. Indeed the surgery of joint wounds has been completely revolutionised, and cases that formerly would have been at once submitted to amputation are now saved without difficulty. This applies not only to incised wounds but equally to those of a lacerated character or that are complicated even with fracture of the articular ends.

To save the joint, three objects must be kept in mind:—first, the synovial cavity must be thoroughly drained; secondly, the joint must be kept perfectly at rest, and firmly fixed; and thirdly, the wound must be prevented from decomposing by some efficient system of drainage.

To drain a joint perfectly, as before stated, is not always possible. Exudation can, without difficulty, be sufficiently drained to prevent the development of tension in its cavity. If an efficient system of drainage can be carried out, minor imperfections of drainage are of less consequence.

Antiseptic treatment of a wounded joint is carried out on exactly the same principles as that of any other wound. The wound must, if necessary, be enlarged; the cavity of the joint is then well syringed out with carbolic acid solution in water (1 to 20), perchloride of mercury (1 in 1000), or some other efficient antiseptic fluid. This is best done by means of a stiffish piece of india-rubber tubing long enough to reach to any part of the joint, fixed on the end of a syringe. The joint may be carefully moved at the same time, so that the lotion may find its way to every part of the articulation. The fluid is then squeezed out of the joint, and efficient drainage provided. This may be done by the use of drainage-tubes, or in many cases these may advantageously be dispensed with and the wound left freely open. If the case be one of a large lacerated wound, with dirt ground into it, it must be carefully cleaned with a sponge. If the wound is in such a situation that it is not likely to drain well, a counter-opening may be made on a probe at the most dependent part, into which another tube may be passed. The antiseptic dressing is then applied and the limb fixed on a splint or by some rigid apparatus in such a way that the slightest movement is impossible. If drainage-tubes have been used they can usually be removed at about the end of the first week, but this will depend upon the amount of discharge. Great care must be taken not to move the joint at the dressings.

One of the forms of absorbent antiseptic dressing, such as sublimate wool-wool, salicylic silk, salicylic or iodoform wool, &c., will be found most convenient in the treatment of wounded joints. The elastic pressure facilitates drainage and limits exudation, while at the same time it aids in maintaining rest. These may be applied as lasting dressings and left undisturbed, unless elevation of temperature, severe pain, or the appearance of discharge shows that all is not going on well. If drainage-tubes have been inserted, the dressing must be changed on the sixth or seventh day to remove them. After the first dressing, if all is going on well, the limb may be fixed in a plaster of Paris bandage, applied over the antiseptic dressing. If there is no elevation of temperature, and no pain, this may be left on till the wound is healed.

Should antiseptics not be available, the following treatment should be adopted. If the joint be opened by a puncture or small clean cut wound, this may occasionally be closed by bringing the edges together, and placing a piece of lint soaked in collodion upon it, or a strip of plaster washed over with resin varnish. The limb must then be placed in a splint (plaster of Paris is the best), so as to be rendered absolutely immovable, and the joint should be surrounded by india-rubber bags containing powdered iodoform, or cold by the application of Leiter's tubes (p. 214). In fact, the best mode of avoiding further mischief lies in the exclusion of air, perfect rest,

and the continuous application of dry cold. In this way inflammation may be prevented, and union of the wound take place under the plaster; but in the majority of cases the injury is followed by so abundant a secretion of synovia that the dressing becomes loosened by the tension and outward pressure of the accumulated fluid which escapes from under it. If, while the dressing remains adherent, the preventive means fail to arrest inflammation, and the joint swell, becoming red, hot, and throbbing, with some constitutional disturbance, the cold applications must be removed and heat substituted in the form of fomentations. The synovial cavity should then be emptied by means of the aspirator. If the fluid that is withdrawn be merely turbid synovia, the hot fomentations may be continued. Opium may be given to alleviate pain. In this way the symptoms may be relieved and the joint recover. Should the fluid withdrawn be pure pus, or contain a large proportion of pus, it is useless any longer to attempt the closure of the wound.

When suppuration has come on, long and free incisions should be made into the joint, on each side, if possible, and at the most dependent part of the capsule, so as to allow a ready exit to the pus. If this be done thoroughly, and perfect rest maintained afterwards, the symptoms are immediately relieved, and ultimately recovery may take place, usually with ankylosis, but occasionally with some degree of mobility. Small incisions into the joint are worse than useless; by a small incision the pus cannot be evacuated from a deep and complicated joint, but air is admitted, and the result is to favour the decomposition of the discharges, and to cause severe septic fever and possibly pyæmia; by making free and early incisions, however, and thus establishing perfect drainage, but little decomposable matter is left in the cavity of the joint, and the evils of decomposition are reduced to a minimum. The complete relief of tension effected by such incisions reduces the local inflammation and saves the patient much pain. After the incisions have been made, it is better to avoid poulticing or simple water-dressing, as these favour putrefaction. The wound must be syringed with some antiseptic solution, as Condy's fluid, carbolic lotion (1 in 40), perchloride of mercury (1 in 2000), or tincture of iodine and water (3j to 0j), and it must be dressed with carbolic oil (1 in 10), or terebene and oil (1 in 6), or a strong lead and spirit lotion. If boric acid lint be at hand, it forms a most efficient dressing, applied warm like a poultice and changed frequently. In the absence of all antiseptic material the open treatment, or the simple application of oil or lard, will be the best. If the case proceed favourably, the discharge will gradually lessen, and the constitutional disturbance subside. The joint must then be placed in such a position, that, when ankylosis results, the limb may be serviceable to the patient. If, however, as very frequently happens when the larger joints are wounded, the suppuration within the articulation, and the abscesses that form outside it, reduce the patient to a hectic state, secondary amputation speedily becomes inevitable.

WOUNDS OF INDIVIDUAL JOINTS.—To the preceding general principles I have little to add with respect to wounds of individual joints.

The **Hip and Shoulder** are so deeply placed, and so well protected, that they can scarcely be wounded except as the result of gun-shot injury, the treatment of which has already been discussed (pp. 360, 366).

Wound of the **Knee-joint** is one of the most common and most severe of such injuries. Those caused by gun-shot violence have already been

described (p. 361). When produced by a puncture or a clean cut, antiseptic treatment and immobility will usually ensure a cure without the functions of the joint being in any way impaired. Thomas's knee-splint will be found the most convenient form of apparatus for fixing the joint. Should suppuration occur, the joint must be laid open unsparingly. The finger should be inserted at the original wound, if it be situated towards the front of the joint, and pushed down to the most dependent part of the synovial pouch; here the tip of the finger may be made to project and be cut down upon. A probe-pointed bistoury is then to be introduced and the incision extended till it reaches from the head of the tibia to the upper limit of the synovial pouch. The knife should be slanted backwards so as to facilitate drainage. The opposite side of the joint must then be treated in the same way. Even after this amputation may be necessary, and the incisions above described can be used in the operation. If the drainage is inefficient, abscesses will often form deeply, the pus bursting from the joint by the upper part of the synovial pouch, and burrowing up the thigh under the vasti, reaching sometimes as high as the trochanter before it is detected. At the time the synovial pouch gives way the relief of tension may cause a deceptive abatement in the severity of the symptoms: but soon the limb swells up to the trochanters, becomes tense, painful, hot, and œdematous, with great constitutional disturbance and high fever, though the joint may be but little swollen, and many days will often elapse before fluctuation can be again felt in it or in the thigh. This absence of swelling in the knee itself may mislead an inexperienced practitioner. At length the abscess may approach the surface near the knee, and, on an incision being made, an immense quantity of pus is discharged. It is the depth in the limb at which the abscess is seated that gives rise to the difficulty in its detection, the violent constitutional disturbance it occasions, and its extreme danger. I have never seen abscess form amongst the muscles of the leg as a consequence of injury of the knee-joint, unless the tibia had been fractured as well as the joint opened.

For the penetration of the knee-joint by needles, see p. 342.

Wounds of the **Elbow** and **Ankle-joints**, when simple, as in punctures, usually admit of closure and of being healed, leaving a sufficiently useful and mobile articulation. When they are complicated with fracture of the neighbouring bones, the soft parts not being too extensively injured, resection of the wounded articulations is the proper course to adopt; if there be much laceration of soft parts with comminution of the bones, amputation, especially in the case of the ankle, will be required.

Wounds of the **Wrist-joint** are peculiarly dangerous, on account of the extent and complexity of the synovial membrane that enters into its conformation. Should suppuration be set up, some of the carpal bones may necrose. In these circumstances, if the patient be in good health and not too old, excision of the joint will leave a very useful hand; when excision is not practicable, amputation must be performed, if possible, by a flap taken from the palm, only the diseased articular ends of the radius and ulna being removed. In some cases the patient may recover without operation, but a stiff and comparatively useless hand will generally be left.

DISLOCATIONS will be described in Chapter XXII.

CHAPTER XX.

FRACTURES.

A FRACTURE may be defined as a sudden and violent solution of continuity in a bone : but by the term "fracture" it is convenient to describe other lesions, which, strictly speaking, are not comprised in the definition. The displacement of an epiphysis from the shaft of a bone is not really a *fracture* but a *separation* ; as is also the displacement of a costal cartilage from a rib.

CAUSES.—Fractures are almost invariably the result of local causes, but the liability to their occurrence is modified by certain predisposing circumstances.

Local Causes.—Fractures may be the result of external violence, or muscular action.

External violence may be applied in two ways : directly or indirectly.

The worst forms of fracture are occasioned by **direct external violence** crushing and splintering the bone, as by the passage of a heavy wheel or by a gun-shot injury. The fracture always occurs at the point to which the force is applied and is often complicated with considerable mischief to the soft parts.

Indirect violence may break a bone in two ways. One that is more commonly talked of than seen is by *contrecoup*, in which, when a blow is inflicted on one part, the shock that is communicated expends its violence on the opposite point, where the fracture consequently occurs. This form of injury has been described only in the bones of the head. (See Chap. XXIV.)

In the other form the bone is broken by being snapped, as it were, between a resisting medium at one end, and the weight of the body on the other. Thus, a person jumping from a height and alighting on his feet may break his legs by their being compressed between the weight of the body above and the ground below. The long bones are those which are most frequently fractured in this way ; and the fracture occurs at the greatest convexity, or at their weakest point. When a person jumps from a carriage that is in motion, although the height of the fall be not great, yet its force is considerable, the feet coming violently to the ground and being suddenly fixed, while the body moves with the same velocity as that with which it was being carried onwards in the vehicle. Hence, fractures received in this way are usually severe, and often compound or comminuted.

Muscular action is not an unfrequent cause of fracture of bones into which powerful muscles are inserted : especially the patella, the olecranon process of the ulna and some of the bony prominences, such as the acromion, which are broken in the same way that a tendon is ruptured—by the violent contraction of the muscles attached to them tearing them asunder. It is not often that the long bones are so fractured ; but the humerus has been broken by a person striking at but not hitting another, or by suddenly throwing out

the arm to seize something that was falling ; and the clavicle has been fractured by a rider giving his horse a back-handed blow. In these cases, however, muscular action may not have been the sole cause, the weight of the limb also tending to fracture the bone. Muscular action also aids in the fracture of bones by indirect violence : thus we see that a sober man who makes a violent effort to save himself more often breaks a bone in a fall than a drunken man who falls like a log.

Predisposing Causes.—Some bones are especially liable to be broken as a consequence of their *serving as points of support*. Thus, when a person falls upon the hand, the shock is transmitted from the wrist through the radius, humerus and clavicle, to the trunk : the radius and clavicle, being the weaker bones, are then especially liable to be fractured. So again, the *situation* of a bone, irrespectively of any other circumstance, may predispose it to fracture, the prominent position of the nasal bones, and the exposed situation of the acromion, render these parts peculiarly liable to injury. The *shape* of some bones disposes them to fracture ; thus, a long bone is necessarily more readily broken than a short and thick one ; hence the tibia and femur are more often fractured from falls on the feet than the os calcis. *Certain parts of bones* are more commonly fractured than others. Those parts especially into which powerful muscles are inserted, or that are in exposed situations and hence liable to injury, or have to receive the weight of the falling body, are often broken. Hence the clavicle, the olecranon, and the neck of the femur, are commonly fractured.

Age exercises considerable influence, not only on the general occurrence of fractures, but on the liability of certain bones to be broken. Fractures may occur even in intra-uterine life, and many cases have been recorded in which one or more bones have been broken in the fetus by blows upon the abdomen of the mother during the later months of pregnancy. Intra-uterine fractures may also occur as a consequence of syphilis ; thus Chaussier dissected a syphilitic fetus that had 113 fractures and another with 43. Fractures may occur also during birth, most commonly of the humerus or femur but occasionally of the bones of the skull. These are usually the consequence of instrumental delivery. Some cases that have been described as congenital fractures appear to me rather to be instances of arrest of development or failure of union between the various parts of the bone. These show no disposition to union or the formation of callus and I have never seen any operation such as wiring, scraping, &c. undertaken for their cure with success.

In early age, as the bones are elastic and partly cartilaginous, fractures occur less readily than in advanced life when they have become brittle and earthy. In children fractures frequently occur at the line of junction of the shaft with the epiphysis where ossification has not as yet become perfect. This separation of the epiphysis occurs chiefly at the lower ends of the humerus and femur, sometimes in the radius and other long bones. As age advances, the compact tissue of the shaft becomes denser and harder, but the cancellous structure of the extremities more dilated and looser ; hence fracture of the neck of the femur is especially common in old people. In young persons the bone is usually broken transversely, but fractures taking place at a more advanced period of life are generally oblique, and often comminuted : in adults they also more commonly extend into joints than when occurring in early age. In children, more than one half the fractures

occurring in the upper limb are of the clavicle: and in the lower limb, fracture of the shaft of the femur by indirect violence is of extremely common occurrence.

Sex indirectly influences the liability to fracture, men being more frequently exposed to the causes of this injury than women. In women, the bones that are most commonly fractured are the clavicle, the radius, the tibia, and the neck of the femur; in men, the shafts of the long bones, the cranium, and the pelvis.

From statistical tables of fractures of the upper limb given by Flower, it appears that below five years of age the liability of the two sexes to fracture is equal. After five, the males steadily increase in liability up to middle life. After forty-five, the number of fractures of the upper limb in females exceeds that in males, in consequence of the extreme frequency of fracture of the lower end of the radius in women above middle life.

Side of the Body.—From the statistics of Gurlt, Middeldorpf, Lente and others, it would appear that fractures occur with about equal frequency on the two sides of the body.

Time of Year.—The popular supposition that the bones are more brittle in winter, and hence break more readily than at other seasons, is altogether a mistake: though fractures may be common at this period of the year, from falls being more frequent during frosty weather.

Spontaneous Fractures are those which happen without any very distinct cause, or under the influence of violence that would usually be insufficient to produce such an injury. They arise from various pathological conditions, amongst which the following are the chief. *Atrophy of Bone* occurs naturally in old age, and is, as before stated, a powerful predisposing cause of fracture; but mere senile atrophy seldom reaches such a degree as to lead to spontaneous fracture. In the same way atrophy from want of use may render the bone brittle, so that a very small force may break it, as we occasionally see in attempted reduction of old dislocations. A much more important form of atrophy is that which accompanies certain forms of disease of the central nervous system, especially general paralysis of the insane. Bruns has collected the records of sixty cases of spontaneous fracture occurring in the insane, and amongst these were many instances of multiple fractures. In some of these cases the bones were found to be greatly atrophied, and in one they were easily cut with a knife. General paralysis is not unfrequently complicated by violent maniacal attacks, and in the necessary restraint at these times it has happened that one or more of the patient's bones have been broken although no undue force has been employed. These cases have more than once given rise to charges of cruelty or manslaughter against the keepers in lunatic asylums. Spontaneous fractures occurring in *locomotor ataxy* have been described by Charcot, Weir Mitchell and others. These, like the joint affections of this disease, appear usually to occur in the early stage, before the development of ataxic symptoms. *Mollities ossium* is, as will be seen when that disease is described, often associated with spontaneous fracture. *Rickets* is more often a cause of bending or partial fracture under considerable violence, but cannot be said to be a cause of true spontaneous fracture. *Scurvy* was said by the older writers to cause a general weakness of the bones, but later observations have not confirmed this. In children it is said to predispose to separation of the epiphyses. *Constitutional Syphilis* was formerly believed in some cases to cause a general

and united by the first intention: and the track of the ball must almost inevitably suppurate. The bones are also usually splintered, and foreign bodies of various kinds are introduced into the articulation, hence the most extensive and fatal mischief commonly ensues.

In a case of traumatic septic arthritis, if we have the opportunity of examining the joint, the appearances will vary with the time after the infliction of the injury. At the end of from twenty-four to forty-eight hours the synovial membrane will be found intensely red and injected, its surface lustreless, its fringes swollen; and the cavity will contain a quantity of turbid fluid, still retaining some of the characters of synovia, but thinner than natural, in which microscopic examination would probably reveal the presence of micro-organisms. Later on, at the end of a week or ten days, the synovial membrane will have lost its characteristic appearance, being concealed by granulation-tissue, the surface of which is entirely or in part covered by a thin grey sloughing layer. The cartilages have lost their natural lustre and smoothness, their surfaces are yellowish in colour, and partial erosion will have commenced at the points at which the opposing articular surfaces have been in contact. The ligaments are swollen and softened, and the tissues surrounding the joint oedematous and infiltrated with inflammatory products. Such fluid as the joint contains will be thick pus. In the more advanced stages of the disease, when the joint has been suppurating perhaps for many weeks or even months, it will be found that it is difficult to recognize the synovial membrane, ligaments and capsule, all being lost in the mass of inflammatory products infiltrating their structures, giving them a uniform semi-transparent appearance. The cartilages are perforated in their central parts; at the circumference they have almost the appearance and feel of wet leather. The bones are exposed and are ulcerating superficially, the surface being rough and of a dark-red colour. Occasionally in the latest stages, a tolerable rest has been kept up in the treatment, granulations may have sprung up from the bony surfaces and have coalesced, and there may be some actual osseous union of the opposed surfaces. If recovery does take place in such a case it is effected by complete bony union between the opposing surfaces and gradual absorption of the inflammatory products and development of dense cicatricial tissue around the site of the joint. Microscopic examination shows nothing but the ordinary signs of inflammation in the various structures entering into the composition of the joint.

Symptoms and Effects.—The severity of the wound of a joint depends chiefly on the size of the articulation and the nature of the wound, but is also materially influenced by the age and health of the patient. Small subcutaneous wounds, such as are inflicted in the removal of loose cartilages, may usually be made with perfect safety, if proper antiseptic precautions be taken and the instruments be perfectly clean. But with joints laid open as the result of accidents, everything depends on the prevention of septic arthritis by the establishment of good drainage and the exclusion of the causes of decomposition. This latter condition may be difficult from the presence of dirt or foreign bodies in the cavity of the joint.

If the patient escapes the dangers of septic arthritis and the wound unites by the first intention, there is usually some effusion into its cavity, with heat and pain, which subside in a few days, leaving the articulation weak, tender, and stiff for some considerable time. This period of swelling is one of con-

siderable anxiety to the Surgeon, but if by the third day the symptoms begin to subside, and especially if there be no marked rise of temperature, he may confidently look forward to a speedy recovery. Should septic arthritis supervene, the joint within a few hours of the infliction of the injury, swells, becomes hot and painful, and throbs. The pain steadily increases, becoming tense and excessively severe. If the aperture be large, synovia freely escapes, which soon becomes mixed with inflammatory products. If it be small, little more than a puncture, the joint swells and fills with pus, which will either escape through the original wound or find an outlet for itself, bursting through the capsule and burrowing widely beneath the fascia of the limb before reaching the surface. The swelling at first assumes the outline of the synovial membrane, but as soon as the inflammation has extended to the ligaments it becomes globular or oval. The skin over the joint becomes red and oedematous. The limb is instinctively placed in a position of semiflexion. There are startings in the limb, worse at night, waking the patient should he fall asleep. The pain becomes agonizing should the joint be moved in the slightest degree. The constitutional disturbance becomes very severe, the temperature often rising as high as 105° Fahr. The pulse is rapid and bounding, the tongue dry, the face flushed, and there is frequently delirium at night. The patient may succumb at this stage from the intensity of the septic fever. In other cases he may be early attacked by septicæmia or pyæmia.

If the patient survive this acute period, abscesses form around the articulation, and the discharge from these, as well as from the joint, with the chronic poisoning from absorption of the products of putrefaction, may gradually prove fatal by exhaustion. Should this danger be passed through and the patient eventually survive, it will be with an ankylosed limb, the utility of which is greatly impaired.

Treatment of Wounded Joints.—The first point to be determined must be whether amputation or resection should be performed, or an attempt made to save the injured joint. If the joint have been extensively laid open, with much contusion and laceration, complicated, perhaps, with dislocation or with fracture and splintering of the bones, no attempt to save the joint is likely to succeed. In these unfavourable circumstances, however, in the upper extremity, and even in the ankle, the limb may not unfrequently be preserved. If the bones be comminuted, the removal of splinters and resection of the articular ends may advantageously be practised in many cases, more particularly if the patient be young and sound in constitution and the soft parts not too extensively damaged. But, if these be largely lacerated and widely contused, or if the patient be aged or broken in health, amputation is imperatively called for. This is especially the case when the knee is injured; extensive lacerations of the joint, if complicated with dislocation, or with comminution of the bones, being cases for immediate amputation.

In all other cases an attempt should be made to save the joint. The prognosis in cases of wounded joints has been greatly improved, and the treatment simplified, by the employment of antiseptics and drainage. Indeed the surgery of joint wounds has been completely revolutionised, and cases that formerly would have been at once submitted to amputation are now saved without difficulty. This applies not only to incised wounds but equally to those of a lacerated character or that are complicated even with fracture of the articular ends.

If then it be determined to save the joint, three objects must be kept steadily in view: first, *the synovial cavity must be thoroughly drained*; secondly, *the joint must be kept perfectly at rest, and firmly fixed*; and thirdly, *the discharges must be prevented from decomposing by some efficient system of antiseptic treatment*. To drain a joint perfectly, as before stated, is not always easy, but every articulation can, without difficulty, be sufficiently drained to prevent the development of tension in its cavity. If an efficient system of antiseptic treatment can be carried out, minor imperfections of drainage are, however, of less consequence.

The Antiseptic Treatment of a wounded joint is carried out on exactly the same principles as that of any other wound. The wound must, if necessary, be enlarged: the cavity of the joint is then well syringed out with carbolic acid solution in water (1 to 20), perchloride of mercury (1 in 1000), or some other efficient antiseptic fluid. This is best done by means of a stiffish piece of india-rubber tubing long enough to reach to any part of the joint, fixed on the end of a syringe. The joint may be carefully moved at the same time, so that the lotion may find its way to every part of the articulation. The fluid is then squeezed out of the joint, and efficient drainage provided. This may be done by the use of drainage-tubes, or in many cases these may advantageously be dispensed with and the wound left freely open. If the case be one of a large lacerated wound, with dirt ground into it, it must be carefully cleaned with a sponge. If the wound is in such a situation that it is not likely to drain well, a counter-opening may be made on a probe at the most dependent part, into which another tube may be passed. The antiseptic dressing is then applied and the limb fixed on a splint or by some rigid apparatus in such a way that the slightest movement is impossible. If drainage-tubes have been used they can usually be removed at about the end of the first week, but this will depend upon the amount of discharge. Great care must be taken not to move the joint at the dressings.

One of the forms of absorbent antiseptic dressing, such as sublimate wool-wool, salicylic silk, salicylic or iodoform wool, &c., will be found most convenient in the treatment of wounded joints. The elastic pressure facilitates drainage and limits exudation, while at the same time it aids in maintaining rest. These may be applied as lasting dressings and left undisturbed, unless elevation of temperature, severe pain, or the appearance of discharge shows that all is not going on well. If drainage-tubes have been inserted, the dressing must be changed on the sixth or seventh day to remove them. After the first dressing, if all is going on well, the limb may be fixed in a plaster of Paris bandage, applied over the antiseptic dressing. If there is no elevation of temperature, and no pain, this may be left on till the wound is healed.

Should antiseptics not be available, the following treatment should be adopted. If the joint be opened by a puncture or small clean cut wound, this may occasionally be closed by bringing the edges together, and pinning a piece of lint soaked in collodion upon it, or a strip of plaster washed over with resin varnish. The limb must then be placed in a splint (plaster of Paris is the best), so as to be rendered absolutely immovable, and the joint should be surrounded by india-rubber bags containing pounded ice, or kept cold by the application of Leiter's tubes (p. 214). In fact, the best chance of avoiding further mischief lies in the exclusion of air, perfect rest,

and the continuous application of dry cold. In this way inflammation may be prevented, and union of the wound take place under the plaster; but in the majority of cases the injury is followed by so abundant a secretion of synovia that the dressing becomes loosened by the tension and outward pressure of the accumulated fluid which escapes from under it. If, while the dressing remains adherent, the preventive means fail to arrest inflammation, and the joint swell, becoming red, hot, and throbbing, with some constitutional disturbance, the cold applications must be removed and heat substituted in the form of fomentations. The synovial cavity should then be emptied by means of the aspirator. If the fluid that is withdrawn be merely turbid synovia, the hot fomentations may be continued. Opium may be given to alleviate pain. In this way the symptoms may be relieved and the joint recover. Should the fluid withdrawn be pure pus, or contain a large proportion of pus, it is useless any longer to attempt the closure of the wound.

When suppuration has come on, long and free incisions should be made into the joint, on each side, if possible, and at the most dependent part of the capsule, so as to allow a ready exit to the pus. If this be done thoroughly, and perfect rest maintained afterwards, the symptoms are immediately relieved, and ultimately recovery may take place, usually with ankylosis, but occasionally with some degree of mobility. Small incisions into the joint are worse than useless; by a small incision the pus cannot be evacuated from a deep and complicated joint, but air is admitted, and the result is to favour the decomposition of the discharges, and to cause severe septic fever and possibly pyæmia; by making free and early incisions, however, and thus establishing perfect drainage, but little decomposable matter is left in the cavity of the joint, and the evils of decomposition are reduced to a minimum. The complete relief of tension effected by such incisions reduces the local inflammation and saves the patient much pain. After the incisions have been made, it is better to avoid poulticing or simple water-dressing, as these favour putrefaction. The wound must be syringed with some antiseptic solution, as Condy's fluid, carbolic lotion (1 in 40), perchloride of mercury (1 in 2000), or tincture of iodine and water (3ij to 0j), and it must be dressed with carbolic oil (1 in 10), or terebene and oil (1 in 6), or a strong lead and spirit lotion. If boric acid lint be at hand, it forms a most efficient dressing, applied warm like a poultice and changed frequently. In the absence of all antiseptic material the open treatment, or the simple application of oil or lard, will be the best. If the case proceed favourably, the discharge will gradually lessen, and the constitutional disturbance subside. The joint must then be placed in such a position, that, when ankylosis results, the limb may be serviceable to the patient. If, however, as very frequently happens when the larger joints are wounded, the suppuration within the articulation, and the abscesses that form outside it, reduce the patient to a hectic state, secondary amputation speedily becomes inevitable.

WOUNDS OF INDIVIDUAL JOINTS.—To the preceding general principles I have little to add with respect to wounds of individual joints.

The **Hip and Shoulder** are so deeply placed, and so well protected, that they can scarcely be wounded except as the result of gun-shot injury, the treatment of which has already been discussed (pp. 360, 366).

Wound of the **Knee-joint** is one of the most common and most severe of such injuries. Those caused by gun-shot violence have already been

described (p. 361). When produced by a puncture or a clean cut, antiseptic treatment and immobility will usually ensure a cure without the function of the joint being in any way impaired. Thomas's knee-splint will be found the most convenient form of apparatus for fixing the joint. Should suppuration occur, the joint must be laid open unsparingly. The finger should be inserted at the original wound, if it be situated towards the front of the joint, and pushed down to the most dependent part of the synovial pouch: here the tip of the finger may be made to project and be cut down upon. A probe-pointed bistoury is then to be introduced and the incision extended till it reaches from the head of the tibia to the upper limit of the synovial pouch. The knife should be slanted backwards so as to facilitate drainage. The opposite side of the joint must then be treated in the same way. Even after this amputation may be necessary, and the incisions above described can be used in the operation. If the drainage is inefficient, abscesses will often form deeply, the pus bursting from the joint by the upper part of the synovial pouch, and burrowing up the thigh under the vasti, reaching sometimes as high as the trochanter before it is detected. At the time the synovial pouch gives way the relief of tension may cause a deceptive abatement in the severity of the symptoms: but soon the limb swells up to the trochanters, becomes tense, painful, hot, and oedematous, with great constitutional disturbance and high fever, though the joint may be but little swollen, and many days will often elapse before fluctuation can be again felt in it or in the thigh. This absence of swelling in the knee itself may mislead an inexperienced practitioner. At length the abscess may approach the surface near the knee: and, on an incision being made, an immense quantity of pus is discharged. It is the depth in the limb at which the abscess is seated that gives rise to the difficulty in its detection, the violent constitutional disturbance it occasions, and its extreme danger. I have never seen abscess form amongst the muscles of the leg as a consequence of injury of the knee-joint, unless the tibia had been fractured as well as the joint opened.

For the penetration of the knee-joint by needles, see p. 342.

Wounds of the **Elbow** and **Ankle-joints**, when simple, as in punctures, usually admit of closure and of being healed, leaving a sufficiently useful and mobile articulation. When they are complicated with fracture of the neighbouring bones, the soft parts not being too extensively injured, resection of the wounded articulations is the proper course to adopt: if there be much laceration of soft parts with comminution of the bones, amputation, especially in the case of the ankle, will be required.

Wounds of the **Wrist-joint** are peculiarly dangerous, on account of the extent and complexity of the synovial membrane that enters into its conformation. Should suppuration be set up, some of the carpal bones may necrose. In these circumstances, if the patient be in good health and not too old, excision of the joint will leave a very useful hand; when excision is not practicable, amputation must be performed, if possible, by a flap taken from the palm, only the diseased articular ends of the radius and ulna being removed. In some cases the patient may recover without operation, but a stiff and comparatively useless hand will generally be left.

DISLOCATIONS will be described in Chapter XXII.

CHAPTER XX.

FRACTURES.

A FRACTURE may be defined as a sudden and violent solution of continuity in a bone : but by the term "fracture" it is convenient to describe other lesions, which, strictly speaking, are not comprised in the definition. The displacement of an epiphysis from the shaft of a bone is not really a *fracture* but a *separation* : as is also the displacement of a costal cartilage from a rib.

CAUSES.—Fractures are almost invariably the result of local causes, but the liability to their occurrence is modified by certain predisposing circumstances.

Local Causes.—Fractures may be the result of external violence, or muscular action.

External violence may be applied in two ways : directly or indirectly.

The worst forms of fracture are occasioned by **direct external violence** crushing and splintering the bone, as by the passage of a heavy wheel or by a gun-shot injury. The fracture always occurs at the point to which the force is applied and is often complicated with considerable mischief to the soft parts.

Indirect violence may break a bone in two ways. One that is more commonly talked of than seen is by *contrecoup*, in which, when a blow is inflicted on one part, the shock that is communicated expends its violence on the opposite point, where the fracture consequently occurs. This form of injury has been described only in the bones of the head. (See Chap. XXIV.)

In the other form the bone is broken by being snapped, as it were, between a resisting medium at one end, and the weight of the body on the other. Thus, a person jumping from a height and alighting on his feet may break his legs by their being compressed between the weight of the body above and the ground below. The long bones are those which are most frequently fractured in this way ; and the fracture occurs at the greatest convexity, or at their weakest point. When a person jumps from a carriage that is in motion, although the height of the fall be not great, yet its force is considerable, the feet coming violently to the ground and being suddenly fixed, while the body moves with the same velocity as that with which it was being carried onwards in the vehicle. Hence, fractures received in this way are usually severe, and often compound or comminuted.

Muscular action is not an unfrequent cause of fracture of bones into which powerful muscles are inserted : especially the patella, the olecranon process of the ulna and some of the bony prominences, such as the acromion, which are broken in the same way that a tendon is ruptured—by the violent contraction of the muscles attached to them tearing them asunder. It is not often that the long bones are so fractured ; but the humerus has been broken by a person striking at but not hitting another, or by suddenly throwing out

at the point of fracture, are more or less extensively lacerated: the periosteum is as a rule completely torn through, and separated from the broken ends for a short distance on one or both sides, leaving a ragged edge. In some cases the periosteum on one side may be intact, and it is said to have been found intact even in complete fractures. As a rule it remains uninjured over a simple fissure. Blood will be found extravasated also in the medullary canal lined up with the fat.

The Period of Inflammation and Exudation.—The first changes observed after the injury are the ordinary signs of inflammation—hyperæmia, swelling, and abundant exudation. This affects the whole of the injured soft parts, so that by the third or fourth day the fracture will be found to be surrounded by a greyish-red, soft mass, not sharply defined, but infiltrating the neighbouring tissues: the torn ends of the muscles are pale in colour from the exudation between the fibres; the areolar tissue is no longer clearly recognizable, its spaces being filled by the coagulated inflammatory exudation; the outer part of the periosteum is in like manner swollen and scarcely recognizable, and the inner layer is so soft and swollen as to be almost gelatinous; the whole membrane can be stripped from the bone with unnatural ease for some distance from the seat of fracture. In the midst of the exudation, patches of unaltered blood-clot will still be seen, but a great part of the extravasation in the immediate neighbourhood of the fracture will have already been partly discoloured.

Microscopic examination at this stage shows the usual appearances of inflammation: the vessels are distended with blood, and all the spaces of the tissues are filled with wandering white corpuscles, either closely in contact with each other, or separated by a small quantity of homogeneous or fibrous intercellular substance.

In the medulla the fat has disappeared from the immediate neighbourhood of the injury, and its place is taken by an exudation similar to that lying externally.

The growth of the soft provisional callus.—During this stage the excess of the inflammatory exudation and the remainder of the blood-clot in the neighbourhood of the injury are absorbed, and there is gradually developed round the ends of the broken bone a fusiform mass, holding them together with some degree of firmness. At first this is soft, almost jelly-like, and homogeneous in appearance, and the ends of the torn periosteum become lost in it. This soft provisional callus presents under the microscope the ordinary appearance of granulation tissue, but close to the bone many cells are found of larger size than the rest, and having one or more nuclei surrounded by a finely granular protoplasm. These *osteoblasts* are usually oval or spindle-shaped, or sometimes angular in form. They play, as we shall see, a most important part in the process of repair, and probably take their origin in the deeper layers of the swollen periosteum.

The callus next increases in density, and the superficial part undergoes the ordinary changes of the conversion of granulation tissue into fibrous tissue, thus forming the fibrous part of the new periosteum covering the callus. The changes which occur in the deeper parts of the provisional callus differ according to its situation. They are thus described by Bruns. In the part distant from the line of the fracture, lime salts are deposited in the form of trabeculae in the intercellular ground-substance. These trabeculae

occurring in the upper limb are of the clavicle: and in the lower limb, fracture of the shaft of the femur by indirect violence is of extremely common occurrence.

Sex indirectly influences the liability to fracture, men being more frequently exposed to the causes of this injury than women. In women, the bones that are most commonly fractured are the clavicle, the radius, the tibia, and the neck of the femur; in men, the shafts of the long bones, the cranium, and the pelvis.

From statistical tables of fractures of the upper limb given by Flower, it appears that below five years of age the liability of the two sexes to fracture is equal. After five, the males steadily increase in liability up to middle life. After forty-five, the number of fractures of the upper limb in females exceeds that in males, in consequence of the extreme frequency of fracture of the lower end of the radius in women above middle life.

Side of the Body.—From the statistics of Gurli, Middeldorpf, Lente and others, it would appear that fractures occur with about equal frequency on the two sides of the body.

Time of Year.—The popular supposition that the bones are more brittle in winter, and hence break more readily than at other seasons, is altogether a mistake; though fractures may be common at this period of the year, from falls being more frequent during frosty weather.

Spontaneous Fractures are those which happen without any very distinct cause, or under the influence of violence that would usually be insufficient to produce such an injury. They arise from various pathological conditions, amongst which the following are the chief. *Atrophy of Bone* occurs naturally in old age, and is, as before stated, a powerful predisposing cause of fracture; but mere senile atrophy seldom reaches such a degree as to lead to spontaneous fracture. In the same way atrophy from want of use may render the bone brittle, so that a very small force may break it, as we occasionally see in attempted reduction of old dislocations. A much more important form of atrophy is that which accompanies certain forms of disease of the central nervous system, especially general paralysis of the insane. Bruns has collected the records of sixty cases of spontaneous fracture occurring in the insane, and amongst these were many instances of multiple fractures. In some of these cases the bones were found to be greatly atrophied, and in one they were easily cut with a knife. General paralysis is not unfrequently complicated by violent maniacal attacks, and in the necessary restraint at these times it has happened that one or more of the patient's bones have been broken although no undue force has been employed. These cases have more than once given rise to charges of cruelty or manslaughter against the keepers in lunatic asylums. Spontaneous fractures occurring in *locomotor ataxy* have been described by Charcot, Weir Mitchell and others. These, like the joint affections of this disease, appear usually to occur in the early stage, before the development of ataxic symptoms. *Mollities ossium* is, as will be seen when that disease is described, often associated with spontaneous fracture. *Rickets* is more often a cause of bending or partial fracture under considerable violence, but cannot be said to be a cause of true spontaneous fracture. *Scurvy* was said by the older writers to cause a general weakness of the bones, but later observations have not confirmed this. In children it is said to predispose to separation of the epiphyses. *Constitutional Syphilis* was formerly believed in some cases to cause a general

brittleness of the osseous system, but there is no evidence in proof of this in every case in which syphilis is a cause of spontaneous fracture some definite local disease, as caries, necrosis, or a gumma, is met with. In the same way the "*cancerous cachexia*," apart from the development of a secondary tumour in the bone, never causes spontaneous fracture. A *sarcoma* growing in or on a bone, or pressing on it when springing from a neighbouring structure, may so weaken it as to cause it to give way. *Hydatid cysts of bone* are extremely rare in this country, but a few cases have been recorded in which they were a cause of spontaneous fracture. *Necrosis, caries and abscess of bone* have all been known to give rise to fracture, but such a complication is very uncommon. Some rare cases have been described in which there is a *hereditary tendency* to fracture of the bones, transmitted from father to son, without any other recognizable constitutional defect. Thus Greenish records a case in which the grandfather had had several bones broken: of his three sons and two daughters, the youngest son and the two daughters escaped without fractures: the eldest son, who had one bone broken, had two children, the eldest of whom had thirteen, and the younger two, fractures: the second son, who had two fractures, had five children, who suffered respectively four, four, eight, four, and three broken bones. Lastly, certain cases are met with in which no clear causes can be found: thus fracture of the femur has more than once been met with in young men apparently quite healthy, from the sudden and violent contraction of the thigh muscles, as for instance in pulling off or drawing on a boot, and I have known a gentleman a little over fifty, apparently in perfect health, break his thigh with a loud snap whilst turning in bed. In cases of spontaneous fracture union rarely takes place, or not without much difficulty.

VARIETIES.—Fractures present important varieties as to their *Nature* and their *Direction*.

Nature.—Fractures are divided first into three classes, *Simple, Compound and Complicated*. A fracture is said to be **Simple** when it is not accompanied by an open wound communicating directly with the seat of fracture.

When the soft parts are torn through, so that the fracture communicates by a wound with the surface of the body, it is said to be **Compound**. A fracture may be rendered compound in three ways: 1. Through laceration of the soft parts by the same injury that breaks the bone, as by a bullet in traversing a limb. 2. By the protrusion of one of the fragments through the integuments. This necessarily most frequently happens when the fragments are sharp and pointed, and the coverings thin, as in fracture of the tibia, and may be occasioned by muscular contraction, by some incautious movement on the part of the patient, or by roughness on the part of those lifting or carrying him. 3. By the sloughing of bruised tissues or by the gradual ulceration of a projecting fragment through the skin.

It is important to distinguish between fractures that are primarily compound, that is, that are compound from the first, and those in which a wound leading to the broken bone forms some time after the accident, as the result of inflammation, suppuration, and sloughing, or from other causes. When the fracture becomes compound secondarily, the danger is greatly lessened on account of the reparative tissue that has formed at the seat of the injury having closed the medullary canal in such a way that septic osteomyelitis is not likely to occur. The blood-clot and the early exudation are also to a great

extent absorbed and the intermuscular spaces around sealed by coagulated inflammatory exudation or granulation-tissue, and thus deep burrowing of septic matter in the limb is not likely to take place, and the danger of septic absorption or pyæmia is greatly diminished.

A fracture is said to be **Complicated** when the injury to the bone is conjoined with some other condition which is perhaps of more importance than the mere fracture, and often greatly influences the result of the case. Thus, a fracture may be complicated with injury of an important internal organ—as of the brain, lung, or bladder—usually inflicted by one of the fragments. A fracture may also be complicated with the wound of one of the principal arteries, especially in the leg, where the tibial vessels lie in close contact with the bone, and are sometimes torn by the broken ends. In other cases again, the fracture is associated with injury of a joint or with dislocation.

Fractures are also divided into the **Single Fracture**, where the bone is merely broken across, split, or fissured; the **Comminuted** (Fig. 158), where the bone is broken into several fragments at one place; the **Impacted**, where one fragment is wedged into another, the compact tissue being driven into the cancellous; and the **Multiple**, where there are more fractures than one, either in different bones or in different parts of the same bone.

Besides these varieties of fracture, it occasionally happens that a bone is only cracked, or partially broken. This especially occurs in the bending of bones in children, in which cases the fracture may be **Partial** or **Incomplete**, merely extending across the convexity of the curve made by the bone. This is commonly called the “*green-stick*” fracture.

Direction.—The direction assumed by fractures varies greatly, and depends materially on the cause of the injury, as well as upon the bone that is fractured. The line of fracture may run through a bone in three different directions: either *transversely*, *obliquely*, or *longitudinally* to its axis.

The **Transverse Fracture**, when met with in the shaft of a long bone, is usually the result of direct violence, and may therefore be accompanied by considerable injury to the soft parts. In this situation it is always more or less toothed and irregular. It is more commonly met with at the articular ends of the long bones, as at the lower end of the radius, the upper end of the humerus or the neck of the femur, and it is then almost invariably caused by indirect violence. In children it often occurs between the epiphyses and the shaft of a long bone. In the patella transverse fracture is the common form met with as a result of violent muscular action, while in the vertebræ and sternum it is usually produced by indirect violence. In the long bones a transverse fracture unites readily and with but little displacement.

The **Oblique Fracture** commonly occurs from indirect violence; the breaking force being applied to the ends, and not across the shaft. It often runs a long way, sometimes nearly half the length of the shaft of a bone, and is more dangerous than the transverse, owing to the obliquity of the fracture causing the ends of the bone to be sharply pointed (Fig. 159), and thus

Fig. 158. — Comminuted Fracture made by gunshot.

described (p. 361). When produced by a puncture or a clean cut, antiseptic treatment and immobility will usually ensure a cure without the functions of the joint being in any way impaired. Thomas's knee-splint will be found the most convenient form of apparatus for fixing the joint. Should suppuration occur, the joint must be laid open unsparingly. The finger should be inserted at the original wound, if it be situated towards the front of the joint, and pushed down to the most dependent part of the synovial pouch; here the tip of the finger may be made to project and be cut down upon. A probe-pointed bistoury is then to be introduced and the incision extended till it reaches from the head of the tibia to the upper limit of the synovial pouch. The knife should be slanted backwards so as to facilitate drainage. The opposite side of the joint must then be treated in the same way. Even after this amputation may be necessary, and the incisions above described can be used in the operation. If the drainage is inefficient, abscesses will often form deeply, the pus bursting from the joint by the upper part of the synovial pouch, and burrowing up the thigh under the vasti, reaching sometimes as high as the trochanter before it is detected. At the time the synovial pouch gives way the relief of tension may cause a deceptive abatement in the severity of the symptoms; but soon the limb swells up to the trochanters, becomes tense, painful, hot, and œdematous, with great constitutional disturbance and high fever, though the joint may be but little swollen, and many days will often elapse before fluctuation can be again felt in it or in the thigh. This absence of swelling in the knee itself may mislead an inexperienced practitioner. At length the abscess may approach the surface near the knee, and, on an incision being made, an immense quantity of pus is discharged. It is the depth in the limb at which the abscess is seated that gives rise to the difficulty in its detection, the violent constitutional disturbance it occasions, and its extreme danger. I have never seen abscess form amongst the muscles of the leg as a consequence of injury of the knee-joint, unless the tibia had been fractured as well as the joint opened.

For the penetration of the knee-joint by needles, see p. 342.

Wounds of the **Elbow** and **Ankle-joints**, when simple, as in puncture, usually admit of closure and of being healed, leaving a sufficiently useful and mobile articulation. When they are complicated with fracture of the neighbouring bones, the soft parts not being too extensively injured, resection of the wounded articulations is the proper course to adopt; if there be much laceration of soft parts with comminution of the bones, amputation, especially in the case of the ankle, will be required.

Wounds of the **Wrist-joint** are peculiarly dangerous, on account of the extent and complexity of the synovial membrane that enters into its conformation. Should suppuration be set up, some of the carpal bones may necrose. In these circumstances, if the patient be in good health and not too old, excision of the joint will leave a very useful hand; when excision is not practicable, amputation must be performed, if possible, by a flap taken from the palm, only the diseased articular ends of the radius and ulna being removed. In some cases the patient may recover without operation, but a stiff and comparatively useless hand will generally be left.

DISLOCATIONS will be described in Chapter XXII.

CHAPTER XX.

FRACTURES.

A FRACTURE may be defined as a sudden and violent solution of continuity in a bone: but by the term "fracture" it is convenient to describe other lesions, which, strictly speaking, are not comprised in the definition. The displacement of an epiphysis from the shaft of a bone is not really a *fracture* but a *separation*; as is also the displacement of a costal cartilage from a rib.

CAUSES.—Fractures are almost invariably the result of local causes, but the liability to their occurrence is modified by certain predisposing circumstances.

Local Causes.—Fractures may be the result of external violence, or muscular action.

External violence may be applied in two ways: directly or indirectly.

The worst forms of fracture are occasioned by **direct external violence** crushing and splintering the bone, as by the passage of a heavy wheel or by a gun-shot injury. The fracture always occurs at the point to which the force is applied and is often complicated with considerable mischief to the soft parts.

Indirect violence may break a bone in two ways. One that is more commonly talked of than seen is by *contrecoup*, in which, when a blow is inflicted on one part, the shock that is communicated expends its violence on the opposite point, where the fracture consequently occurs. This form of injury has been described only in the bones of the head. (See Chap. XXIV.)

In the other form the bone is broken by being snapped, as it were, between a resisting medium at one end, and the weight of the body on the other. Thus, a person jumping from a height and alighting on his feet may break his legs by their being compressed between the weight of the body above and the ground below. The long bones are those which are most frequently fractured in this way; and the fracture occurs at the greatest convexity, or at their weakest point. When a person jumps from a carriage that is in motion, although the height of the fall be not great, yet its force is considerable, the feet coming violently to the ground and being suddenly fixed, while the body moves with the same velocity as that with which it was being carried onwards in the vehicle. Hence, fractures received in this way are usually severe, and often compound or comminuted.

Muscular action is not an unfrequent cause of fracture of bones into which powerful muscles are inserted: especially the patella, the olecranon process of the ulna and some of the bony prominences, such as the acromion, which are broken in the same way that a tendon is ruptured—by the violent contraction of the muscles attached to them tearing them asunder. It is not often that the long bones are so fractured; but the humerus has been broken by a person striking at but not hitting another, or by suddenly throwing out

the arm to seize something that was falling; and the clavicle has been fractured by a rider giving his horse a back-handed blow. In these cases, however, muscular action may not have been the sole cause, the weight of the limb also tending to fracture the bone. Muscular action also aids in the fracture of bones by indirect violence: thus we see that a sober man who makes a violent effort to save himself more often breaks a bone in a fall than a drunken man who falls like a log.

Predisposing Causes.—Some bones are especially liable to be broken as a consequence of their *serving as points of support*. Thus, when a person falls upon the hand, the shock is transmitted from the wrist through the radius, humerus and clavicle, to the trunk: the radius and clavicle, being the weaker bones, are then especially liable to be fractured. So again, the *situation* of a bone, irrespectively of any other circumstance, may predispose it to fracture: the prominent position of the nasal bones, and the exposed situation of the acromion, render these parts peculiarly liable to injury. The *shape* of some bones disposes them to fracture; thus, a long bone is necessarily more readily broken than a short and thick one; hence the tibia and femur are more often fractured from falls on the feet than the os calcis. *Certain parts of bone* are more commonly fractured than others. Those parts especially into which powerful muscles are inserted, or that are in exposed situations and hence liable to injury, or have to receive the weight of the falling body, are often broken. Hence the clavicle, the olecranon, and the neck of the femur, are commonly fractured.

Age exercises considerable influence, not only on the general occurrence of fractures, but on the liability of certain bones to be broken. Fractures may occur even in intra-uterine life, and many cases have been recorded in which one or more bones have been broken in the fœtus by blows upon the abdomen of the mother during the later months of pregnancy. Intra-uterine fractures may also occur as a consequence of syphilis; thus Chaussier dissected a syphilitic fœtus that had 113 fractures and another with 43. Fractures may occur also during birth, most commonly of the humerus or femur but occasionally of the bones of the skull. These are usually the consequence of instrumental delivery. Some cases that have been described as congenital fractures appear to me rather to be instances of arrest of development or failure of union between the various parts of the bone. These show no disposition to union or the formation of callus and I have never seen any operation such as wiring, scraping, &c. undertaken for their cure with success.
